Dr. J. T. Eskridge has kindly given me brief notes of three cases in which pressure neuritis existed, twice in the right arm, once in the left, from involvement of the branches of the brachial plexus by pressure of enlarged lymph-glands. Although the bronchial glands could hardly produce such a result, those mentioned above as communicating with, and often secondarily infecting them, might easily do so, and in fact, did in these cases so far as Dr. Eskridge could determine, for all recovered. I quote his closing sentence, for it is full of suggestive thoughts bearing upon our subjects:

"This patient has remained well for a period of about 6 months. The second case has been well for a similar period, while the first remained free from all pain for a period of 18 months, but I understand that his trouble is returning. The first and third cases were evidently due to syphilis; the second, in all probability, to rheumatism. In none of these cases was there any tender-

ness to pressure on the nerves, external to the thorax, but the pain radiated down the nerves, as we find to be the case in pressure neuritis."

The very striking result in Eskridge's second case from the use of antirheumatic remedies convinces me that his theory of their action is correct, namely, that they modify a rheumatic inflammation of the fibrous tissue of the capsule of the gland.

Whatever the explanation, these three cases call our attention sharply to the need of considering syphilis and rheumatism affecting the thoracic glands in cases not otherwise explicable.

I shall merely direct attention to my own recently reported case,¹⁷ in which obstruction of the left primary bronchus, with all the classical signs, was followed by bronchopneumonia of the lung below; expectoration of more than a pint of pus daily, obviously secreted as expectorated, for no signs of an accumulation of pus existed; this ceasing abruptly upon the expectoration of a fleshy mass, undoubtedly a sloughing bronchial gland, with complete recovery in a few weeks. The obstruction of the bronchus in the early stages, and the staphylococcal infection of the lung in the later, were evidently due to the swelling of the gland and its final disintegration by a suppurative process.

Treatment.—The diagnosis of the diseases we are studying, though often obscure, is sufficiently clear, by inference at least, to direct us as to the treatment. In tuberculous and bronchopneumonic enlargements, and those following measles and whooping-cough, codliver oil is the remedy above all to which we must turn, with the hope of influencing these glands as we do those of the neck in scrofulous enlargements. The sirup of iodid of iron should be given if anemia exists. The general tonic and roborant measures indicated in early tuberculosis are of the utmost value here. Such treatment should be long continued, for the danger of development of tuberculous meningitis has been shown to be a grave one. Until the child has fully regained his health and the weight normal for his age, he should be carefully watched, that nothing avoidable may be allowed to interfere with his general health.

Simon and many English physicians insist that counterirritation with iodine is of great value, while arsenic is given internally for its resolvent effect. Creosote is stated by Voelcker to be of great value. Spengler⁶ believes in the use of tuberculin in cases of tuberculosis of the glands if there be no mixed infection. This has not yet met with general approval. For the syphilitic cases the usual iodid treatment should be vigorously pushed.

For the enlargements secondary to malignant growths we can do nothing, and adenitis found as a part of the various blood diseases calls for no measures beyond those otherwise indicated.

In case suppuration takes place, and the pus lies near the surface of the chest, it may be possible to evacuate it by aspiration or incision, although cases are very few in which such a line has been followed. I saw Whitney aspirate in his case unsuccessfully, the glands probably being still too firm to yield fluid, although subsequently the pus was evacuated freely through rupture into the esophagus:—a brilliant diagnosis and a happy result. In a case of my own, seen also by Drs. Elsner, Parkhill, and Bagot, in which the diagnosis yet lies between sarcoma and tuberculosis, probably originating in the mediastinal glands, four exploratory punctures yielded nothing. Some three months subsequently, after

the case had passed from my observation, the swelling at the second left interspace ruptured and discharged pus, so that I now incline to the diagnosis of tuberculous bronchial glands. In this case numbness extended down the left arm, suggesting pressure upon the brachial plexus by communicating glands, as in Eskridge's cases. Edema of the feet not accounted for either by cardiac, renal, or hepatic trouble, nor by anemia, suggested a possible pressure of enlarged glands upon the inferior vena cava, which lessened somewhat under a tonic treatment directed to the possibility of tuberculosis. This case is rich in suggestions rather than in positive results.

Voelcker¹⁴ recommends free exploration by resection of ribs and the use of the needle, although the results of this treatment have not been at all brilliant, all dying shortly after its adoption. Since, however, these measures have been used where extensive cavity-formation and even gangrene of lung have been diagnosed, we should not be discouraged. His suggestion that gangrene in these cases tends to extend downward, so that the operation should be a low one in case of doubt, seems to be sound.

Sudden dyspnea, not otherwise accounted for, especially in a child who, from previous disease involving the respiratory tract, may be suspected of having breaking-down bronchial glands, would call for the same vigorous measures as if a foreign body had been inhaled. Petersen's case, already quoted, is the only successful one within my knowledge, but, in spite of the often rapidly fatal result of the sloughing of a gland into the air-passages, successful removal may follow correct diagnosis in case the patient lives long enough for the attempt.

A very extensive search of the literature leaves me with the conviction that a member of this society, whose case I have reported above, is the only patient who has been reported as having presumably coughed up a sloughing bronchial gland who lived to bear witness of it.

COLORADO CLIMATE: A COMPARATIVE STUDY.

By EDWIN G. DEXTER, Ph.D.,

Professor of Pedagogy, University of Illinois.

IF THERE is any one thing which characterizes a true Coloradoan, it is pride for his climate. He may be proud of his mountains and of the gold output and even of the plurality his State gave Bryan in '96 (if his politics run in that direction), but when he mentions these things once during a journey east, he is in a continually boastful mood about what nature has done for his State in the way of prevailing weather. He may be getting a little afraid of the consumptive who makes it his Mecca, since he is becoming convinced that indigenous phthisis is increasing, yet he is as firmly as ever of the opinion that his is the only climate on earth which will stay the ravages of exotic cases.

Still the fact remains that he has, at times, to apologize for its vagaries. Let a Raymond excursion but strike the State for a few days, or a session of the National Educational, or American Medical Association announce itself, and weather which shames the memory of the oldest inhabitant is on hand; excuses are profuse and the weather man is sufficiently calumniated, but the fact nevertheless remains that the visitor goes away with the belief that conditions are not all they are "cracked up" to be and that even the Colorado climate has its weak spots.

That this latter is true must be acknowledged, for what earthly thing has not and what western thing is not a little overboomed? Yet a dignified and scientific analysis of conditions does not fail in proof of the fact that these same weak spots are fewer and farther between than similar climatic blemishes in most other regions, and that the Coloradoan has some just excuse for his weather pride. In a study which I have recently made of the effect of weather upon mental states,¹ I found it necessary to study very carefully the prevailing meteorologic conditions for the city of Denver, Colorado, and for New York City. It is my intention in this paper, with hardly any allusion to the mental influences disclosed, to state briefly the contrasts and resemblances which the study of the two climates revealed. In the problem alluded to, the mean temperature, barometer and humidity, the total movement of the wind, the character of the day and the precipitation for each day for a long series of years was used. The period for Denver was 5 years (1,816 days). For New York City, 10 years (3,632 days). In both cases the period was sufficiently long to give us the normal prevalence of any definite meteorologic condition. The data were all taken from the records of the United States Weather Bureau at the stations in the two cities.

The first figure used in illustration of this paper shows the monthly means for the Colorado climate and those for the sea level at New York City.

As will be seen, the two curves for temperature run very nearly parallel, the only marked difference being that the heated season for Denver extends a little later in the autumn, giving October a temperature a few degrees warmer than the eastern city.

It will also be noted that the western mean for the hottest months is a little below the other. This fact is undoubtedly due to the cooler nights, the temperature of which is included. A study of maximum temperatures showed the higher temperatures at the middle of the day, for Denver.

MONTHLY MEANS TEMPERATURE

BAROMETER

HUMIDITY.

WIND, TOTAL MOVEMENT.

The barometer curves are of not much value for our present study, because of the difference in altitude. The Denver curve must be read exactly 5 inches below its position on the chart, and other than this indicated difference in pressure perhaps little can be deduced from it. The curves for humidity are, however, of interest. The differences in atmospheric moisture shown by them are well recognized elements of contrast in the two climates. The noticeable fact is prevailing low humidity (dryness) for Denver, compared with the sea level, with the highest mean for the year (June) ten one-hundredths below the lowest (April) for New York. This factor is, however, discussed in connection with other curves later in this paper.

The means for the total movement of the wind (anemometer registration for the month) are, I believe, a veritable surprise to the Coloradoan. If there is any

¹See "Conduct and the Weather," Monograph Supplement, No. 10; *The Psychological Review*; "Crime and the Weather," *Scientific American Supplement*, May, 1899; "The Influence of the Weather upon the Mental State," *Science*, August 11, 1899; "The Influence of the Weather upon Crime," *Popular Science Monthly*, September, 1899.

vulnerable point in his climate he has always supposed it to be the wind. "These horrible winds" and "the windiest place I ever knew" have been common expressions of the newcomer, and the old resident has hardly dared to contradict them. Here, however, we

FIG. 2.

have irrefutable evidence to the contrary, for these figures were taken from the Weather Bureau's records for 21 years. Yet the highest movements for Denver (March and April) are less than the lowest for New York (July and August), and the average for the year 2,000 miles per month less. The eastern March, with

obscured; and "Cloudy" if eight-tenths or more. In this table under precipitation "Wet" days (those having rain or snow) are compared with "Dry" (those without either) without taking into consideration the amount of downfall. The percentages of days of this character are read by reference to the scale at the left.

The actual precipitation for New York City is about $3\frac{1}{2}$ times that for Denver.

As will be seen by a glance at the curves, the latter city has 42% of clear days to 27% for New York. The partly cloudy days are about equal, while the eastern city has about double the number of cloudy days. About this same relation exists too for days upon which precipitation was registered (Denver 16%, New York 37%).

In this paper no charts are shown either for temperature or barometer. The former is left out, since the monthly means for the two cities so nearly coincide that there could be but little difference between the conditions when tabulated in percentages. The latter, since the difference in altitude is such that when five inches are subtracted from the New York readings we practically have those for Denver. However interesting the difference in density of the atmosphere thus indicated may be, and however valuable to the sufferer from any pulmonary trouble, it remains pretty nearly constant and would fail to show in any important manner upon curves constructed as these are.

With the humidity, however, it is different. If the Colorado air has any therapeutic value, it is because of

FIG. 3.

its 8,800 miles, fairly puts to shame its western contemporary, and the patriotic Denverite can add one more arrow—perhaps an unexpected one—to his quiver. It is true that the anemometer at the New York station stands about 75 feet higher than the one at Denver, but this difference can hardly account for the difference in registration.

Yet it must be conceded that in one respect the western wind is more disastrous than that of the east. The studies referred to prove conclusively that its mental effects are greater. During high winds the prevalence of suicide and of murder, also of misdemeanors in the public schools, ran up to 6 or 8 times the normal; while for the east the increase in all but suicide was found to be slight for such conditions. This was hypothetically accounted for by reference to the high electric potential of the atmosphere at such times. (See "Conduct and the Weather.")

Figure 2 shows the relative prevalence of "Clear," "Pt. Cloudy," and "Cloudy" days, and also those with and those without precipitation for the two climates studied. A day is characterized by the Weather Bureau as "Clear" if three-tenths or less of its possible sunshine hours (those from sunrise to sunset) are obscured; as "Pt. Cloudy" if from four-tenths to seven-tenths are

its dryness, and the relative conditions of humidity are shown upon Figure 3.

In it the numbers at the top indicate conditions of humidity, and the percentage of days under each are to be read by means of the scale at the left. For example, 5% of the days were found to have had a mean humidity of between 5 and 10 (hundredths) at Denver (none of that character at New York); 7% between 10 and 20; 10% between 10 and 15, and so on as indicated by the

FIG. 4.

curves for the two cities. A mere glance at the relative position of the two curves is sufficient to show the excessive dryness of the western compared with the eastern city, and tells more than whole pages of text can do—for humidities below 50, many times more days at

Denver than at New York, and for those above 75, the reverse relation.

The facts shown upon Fig. 4 are perhaps of not much importance from the therapeutic standpoint, but are inserted because they seem so inexplicable to one who has been familiar with the climates compared. The figure is constructed exactly as the preceding, except that conditions of wind are indicated at the top instead of those of humidity. The relation of the curves tells the whole story, showing 18% of the days at Denver, with a total movement of between 50 and 100 miles (practically calm) to less than 1% for New York, and the same deficiency of movement is shown all the way through.

It may be argued that the local nature of this study lessens its value, and that is undoubtedly more true for the wind than for any of the other meteorologic conditions discussed. Denver is only about 15 miles from the foothills and there is little doubt that the movement there is less than for other more exposed positions on the plains. Yet the other larger Colorado cities which figure to any extent as health resorts, as Colorado Springs and Pueblo (the former much nearer the mountains than Denver), are under practically the same conditions, and the study, I believe, is valid for the health region of Colorado. New York, too, is a typical eastern seacoast city, and the comparison would probably be equally as true for any other.

In conclusion I wish to say that I am not a physician. I have no selfish interest in wishing to exploit the virtues of the Colorado climate. Members of the medical profession may be able to interpret the plain facts here presented into terms of health for some unfortunate. If so, the mission of the study will have been fulfilled.

PUBLIC EDUCATION AND THE PREVENTION OF DISEASE.

By H. L. JOHNSON, M.D.,
of Franconia, N. H.

It requires no very discerning mind to see that preventive medicine is the banner under which our profession must march in order to bestow upon mankind the highest fruits of its labors. The brightest aspect of the many rapid strides, which in recent years have been made in medicine, is the increasing importance that is being accorded to the prophylaxis of disease. The brilliant work of the pathologist, made possible through the perfection of our modern instruments, has placed at our disposal the knowledge and weapons which enable us to meet disease upon its own grounds; to oftentimes anticipate and assume the aggressive, instead of blindly awaiting the attack. From the mere empiricism of former times the practice of medicine has arisen to the dignity of a science, and as such is daily adding to the list of achievements that have made our profession second to none other in honor and usefulness.

When we consider the loss of time, the expense, the privation and suffering that so often follow in the wake of disease, we realize that to prevent even a small part of the many ills to which flesh is heir, is an object worthy of the most strenuous efforts.

The brilliant results already accomplished in limiting the ravages of acute contagious diseases require no discussion here. We have but to compare the horrible records of mortality in former times with those of the present, and they will speak eloquently for the science

of medicine. In marked contrast to the energy and scientific manner in which the prophylaxis of acute contagious diseases is carried out, there is apparent a strange apathy and lack of energy toward the prevention of the chronic and more insidious diseases, which, though less rapid and startling in manner of destroying life, yet slay their scores where smallpox, yellow fever, and diphtheria kill one.

While in many respects the present generation may thank its stars for the improved conditions under which we live and carry on business, the situation is not altogether in our favor. The rapid growth of our country, the enormous increase of business due to the development of our natural resources, and the consequent tendency toward the concentration of population about business centers, has greatly altered the national mode of life. From the simple outdoor life of our forefathers, whose task it was to subdue nature, we have become, as the most enthusiastic optimist must admit, a race of dyspeptic money-getters, whose highest ambition is too often the almighty dollar, and whose chief regard for health lies in the fact that its possession assists in the making of money.

It is evident to anyone who will stop to consider, that one of the great social problems of our time, and one that very nearly concerns the welfare of a nation, is the preservation of the highest possible standard of health, physical and mental, among its people. I put physical health first. "*Mens sana in corpore sano*," is an old philosophical dictum so common to our ears that perhaps the ancient adage has lost much of its force. It is a motto, however, which should be emblazoned upon the walls of every home in our land. Given a nation every individual of which should live in the enjoyment of perfect physical and mental health, and it would be easy to conceive such a people dominating the whole world by sheer force of its vitality. "The survival of the fittest," is a doctrine that in the long run must prove true as surely as that a sound body is the necessary complement of a sound mind.

The natural province of the physician is to combat disease: without disease the profession could not exist and the prevention of disease must therefore, to a certain extent, prove self-destructive to the profession. To the honor of our cult be it said, however, that no selfish consideration has ever weighed against the public welfare and never can. The public already owes an immense debt to the careful, conscientious toil of the modern scientific physician, who has freely given for the good of humanity the results of his labors. In the coming years this debt must constantly be increased and in no way can it be more gratefully done than in the promotion of adequate public education in things hygienic and sanitary; in the prevention of disease by the dissemination of knowledge and the dissipation of ignorance.

It is a fact that the masses are far less well-informed in matters pertaining to medicine than in any other branch of science. This condition of things should be remedied, for that ignorance and prejudice are two mighty obstacles in the march of modern hygiene and sanitation, no one, has he ever served on a board of health, will attempt to deny.

There are many ways by which a great deal of much-needed and salutary information may be conveyed to the public in respect to healthful living and the prevention of disease. It is my purpose to touch briefly upon but one—a plea for a better and more scientific method

of instruction in hygiene and sanitation in our public schools. "It is hard to teach old dogs new tricks," and while it is surely fitting to disseminate knowledge as widely as possible, it is to the coming generation rather than to the present that we must look for the best results. That it is possible in a great measure to prevent by proper and rational living such diseases as tuberculosis, the great scourge of mankind, arteriosclerosis, rheumatism, gout, dyspepsia, and a host of other ills, no one will attempt to deny. To be sure there are many who sin wilfully against the laws of health, but sinning through ignorance ought not to be permitted in these days of books and letters; and sinning through carelessness might be made far less common should the proper and needful emphasis in these matters be accorded to the education of every individual.

I believe the physician as an important factor in our public educational scheme has been too long neglected. I believe the coming generation ought not to look in vain to the medical profession as the source of a higher and more rational method of education in the science of healthful living. The nature of his business tends strongly to keep the physician out of public affairs; but the time has come when his voice should be heard in no uncertain tones upon a subject of such vital importance.

That the present system, as now taught, is almost entirely lacking in practical results, as well as in interest to the pupil, is evident. It is true that physiology and hygiene are taught in our public schools, and it is also true that in so far as the benefiting of the public health is concerned, both subjects, as at present handled, might almost as well be dropped. In many States the teaching of hygiene, as required by law, consists mainly of a symposium upon the evil effects of alcohol and tobacco, with enough physiology to demonstrate the series of pseudo-scientific sermonets which are supposed to supply the pupil with sufficient knowledge of things hygienic and sanitary to meet every emergency in life. The average pupil might be pardoned in thinking an unfair advantage had been taken in compelling him to study upon a week-day that which he had been accustomed to consider the especial prerogative of a Sunday temperance lecture. The great majority of teachers, especially in the smaller schools, are almost as ignorant of the subjects of physiology and hygiene as their pupils, and certainly must utterly fail in the attempt to make these branches even of passing interest. A great deal of anatomy is taught in the physiologies that no one but the surgeon need know, and is of no practical use whatever to the ordinary individual. The personal side only of hygiene is taught. There are no textbooks in the country that meet the requirements of these modern times. There is not one teacher in a hundred capable of intelligently teaching these branches of study were such books today placed in our public schools. The result is that these subjects which are of the very highest importance in the education and development of healthy men and women and useful citizens, and are capable of being made most interesting, occupy a position of little importance in our educational scheme, and certainly are productive of almost no practical benefit, in so far as the prevention of disease is concerned and the promotion of better public sanitation.

Is not this a matter that directly concerns the medical profession? We are today struggling for many needed reforms in public sanitation. We are striving to pass through legislature measures of the most vital import-

ance to the integrity of our profession and for the protection of the masses. The greatest stumbling block in our way is the widespread ignorance that prevails among the people in regard to things pertaining to medicine. Why in these enlightened days does there remain so much of the mysticism and superstition that from bygone ages to the present time has characterized the attitude of the laity toward the medical profession? The blind faith reposed alike in the incantations of the Hindoo medicine-man and the remedies of the modern medical quack are a sufficient index to the abysmal ignorance that prevails generally among the people in regard to the simplest laws of health. Why is it possible to sell annually so many millions of dollars' worth of patent medicines? Why do our newspapers reek with filthy advertisements that are a disgrace and a reproach to any civilized nation? Why can any smooth-tongued charlatan grow rich upon the credulity of his fellow mortals? Why is it possible for such fads as "christian science," "osteopathy," "divine healing," and the like, to spring up and flourish? Simply because the majority of the people are profoundly ignorant of their own bodies and the proper way to care for them. They are looking for a miracle and gravitate naturally toward that source that promises the one most wonderful. We look on in amazement at the gullibility displayed by every class and condition of men, and perhaps forget that we are looking through different eyes than theirs; that what is simple to us is darkness to them, and any straw however light which may be wafted toward them is eagerly grasped; one failure of relief makes the next chimera the more acceptable.

What is the remedy for this state of affairs? Can the medical profession hold itself entirely blameless for this condition of ignorance that prevails among an otherwise well-educated and intelligent people? The remedy I believe is simple and may be comprised in the one word—Education. When the science of healthful living receives the attention it deserves in our public schools, when it is made equal in importance, as it should be, with mathematics and the languages, when it is taught practically and systematically from the beginning of the child's education to the time when he receives his college degree, we shall then be in a fair way to rear a generation less susceptible to the germ of the faddist hysteria, less prone to kneel at the shrine of divine healers, and who may even object to the sight of from one to a dozen patent-medicine advertisements upon every telegraph pole, fence, and wall in our country, as unesthetic and unnecessary. Possibly civilization might so far advance as to make it feasible to shut out from our newspapers such advertisements as "Sure relief for ladies," and the thousand infallible remedies for the cure of all weaknesses due to youthful indiscretions. The remedy, I stated, for much of the disease prevalent, both social and physical, is simple. The application of the remedy—the development of a common-sense system of instruction that shall equip the youth of our country with a practical knowledge of personal and public hygiene will be a huge task, but one that certainly ought to be possible of accomplishment.

I am aware that in some of the better and richer schools where the proper appliances may be afforded and where the highest talent is found among the teachers, that instruction in physiology, hygiene and sanitation is slightly more effective, yet still far below the proper standard. Such schools, however, are few in comparison to the hundreds of smaller and poorer ones

where the teaching of these subjects with any degree of effectiveness under the present methods is an utter impossibility, and indeed, where it is regarded as a farce by both teacher and pupils.

For the reformation of this deplorable state of ineffectiveness, two things are essential, both of which are lacking. The first is a thorough, systematic and above all *scientific* system of instruction in hygiene and sanitation. Such a system should comprise a series of textbooks as carefully graded as mathematics or languages. All the ground necessary should be completely covered for a practical mastery of the subjects, and especial attention should be paid to the prevention of disease. All unnecessary matter should be omitted. Less physiology and anatomy should be taught. The simplest elements will suffice and much of the weary memorizing which makes these subjects unpopular with most pupils might be avoided. The child should be early taught the personal side of hygiene. A profound respect for his own body and the proper way to care for it should be inculcated. The importance of good health to his future success in the world should be strongly emphasized. As he grows older, he should be taught that the proper care of his body is not only a personal duty but a public one. He should be made to feel a certain responsibility in the public welfare. He should know that in the prevention of disease and the preservation of health lies one of the greatest safeguards to the nation. All children are easily taught patriotism, and a little patriotism along this line would surely do no harm. The fact that intemperance means something besides the abuse of alcohol and tobacco is certainly worthy of consideration. The pupil might with great advantage be taught that excesses in eating, work or play are directly responsible for the larger share of human ills. He should be made to understand that any practice tending to lower the vitality is but the opening of another road to the easy approach of disease. He should realize without any doubt that his health is his capital in life, which once squandered cannot be regained; and should comprehend that posterity has claims upon him not lightly to be set aside. The germ theory of disease should be introduced to the pupil and the acquaintance kept up. The microscope and camera should be brought into play to practically demonstrate the deadliest enemies to mankind. As he grows older, he should be taught the habitat, manner of growth, and the conditions under which a few of the more important disease-germs flourish, are disseminated, and the avenues by which they finally reach the human body, together with the precautions necessary to avoid them and limit their spread. A sufficiency of this kind of practical knowledge concerning the more prevalent diseases might be as easily taught as botany or geology, and would prove far more useful.

The subject of sanitation should embrace everything that the word implies, from its personal application to its paramount importance in the public welfare of our great cities. This subject should occupy a position second to none in the curriculum of all our colleges and academies. The chair should be held by experts capable of making this branch both interesting and practical. In fact the aim should be to make a practical sanitarian out of every high school and college graduate. His diploma should imply that he is as well grounded accordingly in the subjects of hygiene and sanitation as in any of the other branches of education. I am confident that the introduction of a little "horse sense" in these matters

into the education of the youth of our country will do more to limit disease and promote a higher standard of public health than any other method. The fact that subjects of such vital importance have been so long relegated to the background should be felt as a personal reproach by every physician; and we should neglect no opportunity to rectify the mistake.

Instruction from textbooks should be supplemented by lectures and plain common-sense talks upon matters that may be better handled in this way than by means of books. To this end there are plenty of physicians in our towns and cities able and willing to take up the task. Indeed the medical profession should be in close touch with our public schools.

The medical inspection of schools is a subject that is attracting widespread and favorable notice. Such inspection should include not only the testing of the hearing and eyesight, but should apply to the general physical fitness of every pupil for the pursuit of his studies. There are thousands of children in our public schools, who, through their own ambition or that of misguided parents and friends, are wrecking their nervous systems. Such children are not themselves to blame; but that they should be permitted to do so, is a lasting reproach to their elders. They need more physical culture; more of the ozone of the open fields, and less Greek roots and Latin prose to make of themselves healthy and useful men and women. We are coming too often into contact with nervous breakdowns in the young. It is a pitiful thing that so many of our youth with bright careers opening before them, find themselves either incapable of making the most of opportunities or break down altogether at the critical moment. A little wholesome restraint and wise advice in school and college may do much to lessen the number of disappointed lives, cases of chronic invalidism, insanity and suicide.

The tendency of our modern civilization is strongly toward the neurotic. More bone and sinew is needed to counteract this tendency and to establish a healthier equilibrium between the physical and the mental. There is a growing and salutary importance attached to athletics in all our schools and colleges; but by far the largest share of attention is given to the comparative few in training for the various athletic teams. It is of vastly greater importance that each student should receive the proper share of advice and training demanded by his individual condition, than that the athletic manager should be able to turn out a few highly-trained men capable of winning a signal victory in some athletic contest.

Teacher and physician should work together in perfecting the development of the student's body and mind; to make the most of each and to avoid a misshapen growth of one at the expense of the other; to make of the body a fit and willing servant to a healthy mind; a body free as possible from tendency to disease; a mind capable of appreciating the worth of its servant and on the alert to guard it from decay. When as much care is bestowed upon the pedigree, rearing, development, and education of children as is accorded to blooded stock—if ever civilization shall attain to such a pinnacle of progress—there will come into existence a far more sane, healthy, and happy class of human beings than may today be found upon the face of Mother Earth.

The second essential to a rational system of hygienic education is competent instructors. The fact that so few are capable of teaching hygiene, as it should be

taught, is no fault of the teacher. The fault lies rather in the fact that a branch of science of most vital importance to the public welfare has been kept too long in the background. A superficial book knowledge, and that too often gathered from questionable and unscientific sources, is all that is required of the instructor. The result is precisely as might be expected. The subject is of little interest to the teacher and naturally of less to the pupil. That which should be made interesting and productive of much practical good, becomes a mere drudgery, barren of any result. When hygiene, sanitation and physical culture are given the prominence they deserve in our public schools, when as high a degree of proficiency in these branches as in others is required of teachers, there will be no lack of efficient instructors, for demand, be it strong enough, will produce the supply. I believe it is the duty of the medical profession to make this demand and to present to the public a system of instruction in hygiene and sanitation that may be favorably compared with any of the other branches of science taught in our public schools and colleges. This is a matter which ought to engage the attention of the best minds of our profession. It is time that some influence other than that of publishers and their friends, or a society with an axe to grind, should select the textbooks for our public schools. The preparation of a sensible and practical series of such books placed in our schools and efficiently taught would accomplish far more good than any number of new editions in practice or surgery.

All the labor of the medical profession, whether it be in practice, in teaching, in legislation or the authorship of books, tends ultimately to the public good. Why not strike at the root of the matter and educate the public, especially the coming generation to a higher appreciation of our efforts? We need the hearty and intelligent cooperation of our coming men and women in the struggle against quackery and fraud, the limiting of disease and the thousand evils against which we have fought so long and with mediocre success. We have been handicapped too long by ignorance and prejudice. Let us eliminate as much of it as possible by the cultivation of a soil that has too long laid neglected, and which in the future should be made to yield rich returns.

Surgery of the stomach is reviewed by Carless (*The Practitioner*, November, 1900). He calls attention to the many operations now performed on the stomach, and says **gastrectomy** is indicated only in carcinoma of that organ. This operation has now been performed about 15 times, with 5 deaths so far. Attention is called to the fact that the vagi nerves are severed in gastrectomy, which leads to accelerated action of the heart, and death from cardiac exhaustion has been reported. **Gastroenterostomy** is performed in many cases in which formerly it was not attempted. It is indicated in the following conditions: (1) In cases of gastric ulcer which have not yielded to the ordinary treatment; (2) in hemorrhage from gastric ulcer, which occurs either as an acute or chronic complication; (3) in pyloric stenosis due to gastric ulcer; (4) in pyloric cancer; (5) in atonic dilation of the stomach; (6) in hyperchlorhydria with eructations and heartburn. Using the posterior rather than the anterior wall of the stomach in performing this operation is a great improvement. **Gastroplication** may do much to remedy a chronic dilation of the stomach. It consists in doubling the organ over itself and throwing it into a large horizontal fold. **Gastrostomy** is now frequently performed for any condition which leads to atresia of the esophagus. It should be done under a local anesthetic, as a septic pneumonia is apt to follow a general anesthetic, septic material being regurgitated from the stenosed esophagus. Gastric troubles should be carefully studied. If this were

done greater success would attend the physician's efforts and more cases of carcinoma of the stomach would come to the surgeon in time to be cured. [A.R.C.]

The Etiology of Acute Pneumonia.—Howard (*Cleveland Journal of Medicine*, October, 1900) reports the result of 174 autopsies. Of these, 67 were found to be acute nontuberculous inflammation, of which 14 were primary pneumonia and 53 were secondary pneumonia. The pneumococcus was found in all cases of primary croupous pneumonia, in pure culture in 8, with *Streptococcus pyogenes* in 1, and with *Bacillus mucosus capsulatus* in 1. In the 13 cases of secondary croupous pneumonia the pneumococcus occurred alone in 6 cases, *Streptococcus pyogenes* alone in 2 cases, *Streptococcus pyogenes* and *Staphylococcus aureus* in 2 cases; *Streptococcus pyogenes* and *Bacillus mucosus capsulatus* in 1 case; *Streptococcus pyogenes* and *Bacillus coli* in 1 case, and *Bacillus mucosus capsulatus* in 1 case in pure culture. Thus the pneumococcus occurred alone in nearly 50% of the secondary croupous pneumonias, while the streptococcus was concerned in the etiology of the same number, but occurred alone in only 2 cases. In all 13 cases the pneumonic process was clearly secondary and often accidental. One case of primary **bronchopneumonia** was due to the pneumococcus alone, one to the pneumococcus and bacillus of influenza, and one to the streptococcus and to *Staphylococcus aureus*. In the secondary bronchopneumonias the pneumococcus occurred alone in 8 cases, with *Staphylococcus pyogenes aureus* in 2 cases, with *Bacillus coli* in 1 case, and with streptococcus and *Bacillus mucosus capsulatus* in 1 case; *Streptococcus pyogenes* occurred alone in 4 cases, with *Staphylococcus pyogenes aureus* in 1 case, with *Bacillus mucosus capsulatus* in 1 case; *Staphylococcus pyogenes aureus* occurred alone in 3 cases, with *Staphylococcus albus* in 1 case, and with the pneumococcus in 1 case. *Bacillus mucosus capsulatus* occurred alone in 7 cases, with *Bacillus coli* in 2 cases; *Bacillus coli* occurred alone in 2 cases, with "cocci" in one case and with the pneumococcus in 1 case. [A.B.C.]

The Diagnosis of Ectopic Pregnancy before Rupture.—Baldwin (*St. Louis Courier of Medicine*, October, 1900) says the sharp, colicky pains, the syncope and collapse, at once attract attention and point almost unerringly to ruptured ectopic pregnancy. The author, however, points out that it is dangerous to defer diagnosis until rupture has occurred, and says there are no pathognomonic symptoms of tubal pregnancy, or of any other form of ectopic pregnancy. Usually, however, we find the following points: The patient gives a history of several years of sterility (many exceptions); she has missed a menstrual period, perhaps 2 of them (numerous exceptions); she has noticed some unusual pains in the pelvis, which she will probably describe as boring, griping, or colicky in character, these pains being situated usually in the region of an ovary; she has, perhaps, within a few days of the time of consulting her physician had a more or less irregular hemorrhage; perhaps has discharged pieces of membrane which she supposed indicated an abortion owing to hemorrhage, pain, and suspicion of an existing pregnancy. Possibly, however, there has been no suspicion of a pregnancy, as the woman has accepted her sterility as incurable. On making a vaginal examination, if the conditions are at all favorable the examiner will find upon one side or the other of the uterus, or back of it, a fusiform, well-defined cystic tumor, the size of a pullet's egg or a little larger. This tumor will probably be tender on pressure, symmetric in outline and distinctly pulsating. When the uterus is found somewhat enlarged and having the feel of pregnancy, but not enlarged so much as we would expect, a presumptive diagnosis of tubal pregnancy is warranted, and the matter of an operation should be carefully and without delay considered. There are few conditions which give us the same kind of a tumor as is found in these cases. An enlarged and adherent ovary in Douglas' culdesac cannot, perhaps, be differentiated from a tubal pregnancy in the same location. An old pyosalpinx, a hydrosalpinx, a small cyst of the broad ligament, or an enlarged ovary in its normal location, might be mistaken for an unruptured tubal pregnancy. It is not likely, however, that any of these conditions would be accompanied by symptoms pointing to an ectopic pregnancy, and yet they may; but all these conditions are such as to justify operative interference. DECEMBER 8, 1900

\$3.00 PER ANNUM

To take the hospitals out of politics is the praiseworthy ideal of the advisors and proposers of charter revision in New York City. The movement chiefly relates to the control and management of Bellevue and its subsidiary hospitals, and to some others. The plan is simply to take their government from the Department of Public Charities, and to vest it in a board of seven trustees, appointed by the Mayor, from lists furnished by the presidents of sundry charitable organizations. The benefits from such a change will be all those derived from a permanent and stable administration; benefits both to the hospital and the community, easily recognized, and fully illustrated by the success following its adoption in Boston, Cincinnati, and other cities. The evils thus avoided are those inevitably connected with the administration of hospitals by politicians, medical and lay, interested in the degraded condition of our politics. These also need no enumeration, as they are in horrible evidence everywhere. We trust that the honorable members of the profession, and those medical societies not moribund with apathy and "esprit de corpse" may bestir themselves to further this reform, not only in New York, but wherever it is needed.

Misogyny in Medicine must be looked upon as an incongruity in a liberal profession, but prejudice and tradition die hard. While woman in medicine is no longer a novelty in this country and to a certain extent also in England, her demand for equality with man in this respect has only grudgingly as yet been responded to on the continent of Europe. Nevertheless concessions are gradually being made, and time, which adjusts all things, will see that woman gets her rights. By a recent regulation women are admitted as ordinary students to the universities and colleges of Austria, but when a short time ago a number of them appeared upon the benches before Professor Nothnagel in the Medical Department of the University of Vienna, this distinguished man refused to proceed with his lecture on the somewhat remarkable ground that it had not been prepared for women students. A not dissimilar experience occurred at Gratz. Such things will, however, cease as the novelty of the situation wears off and prejudice yields to common sense. It is not likely that woman will be dislodged from the secure place in medicine she has made for herself.

A Professional Relation to Insurance Companies.

—Good lawyers are aware that a great deal of ill-advised ingenuity and great expense to the community are the result of the attempts of some life-insurance companies to avoid the just payment of policies. It has come to such a pass that no one should now pay a premium without the advice of an astute legal mind upon the question whether in case of death in any way and from any cause the company cannot wriggle out of the payment of the claim. Perhaps the only way to avoid this injustice is professional watchfulness of companies and the preparation of a sort of blacklist of those which habitually exhaust every device to avoid their plain obligations. Here is a work for our apathetic and disorganized medical organizations. Let us suppose that a physician suffers a martyr's death from septicemia in the performance of his professional duty. Should physicians continue to patronize the company that, having accepted his hard-earned premiums, evades its assumed obligations and cheats the widow and children out of the payment of the claim? Many such things have occurred in various parts of the country, and an end should be made of them.

The Abuse of Cross-Examining.—A recent trial in New York, in which a valet sued a young millionaire, was the scene of extraordinary license and abuse by the plaintiff's lawyer. This attorney was permitted by the judge to go to the extreme limits of provocation and insult. A recent correspondent in the *New York Sun* calls attention to the fact that this unbridled license on the part of lawyers in conducting cross-examinations has been made the subject of judicial decision, and that the highest court in that State has on one occasion given a judgment in favor of defenseless witnesses. The very fact, however, that this judgment was given in reversal of the decision of a lower court, shows that there is by no means unanimity among the judges on this subject.

We do not hesitate to say that the chief responsibility for this gross abuse rests with the judges themselves. They have absolute control in the courts, and can call a swaggering lawyer to order in a moment. In medicolegal cases, especially criminal cases, these abuses have been witnessed in our Philadelphia courts, and they are highly discreditable to the cause of justice, and especially to the judges. No one expects aught

else from lawyers of a certain type, but from the judges a rule of severe impartiality and decorum is demanded.

Height and Weight in Life Insurance.—At the fourteenth annual session of the National Fraternal Congress Dr. M. E. Moss presented to the medical section the report of his committee on the subject of heights and weights. The following table gives the average weights of 133,940 applications of selected risks:

HEIGHT	5 ft	1	2	3	4	5	6	7	8	9	10	11 ft	1	2	3	
AGE, 18 to 25	120	122	124	127	131	134	137	142	146	150	154	159	165	170	176	181
“ 25 to 30	125	126	128	131	135	138	142	146	151	155	159	164	170	177	184	190
“ 30 to 35	128	129	131	134	137	141	145	150	154	159	164	169	175	181	188	195
“ 35 to 40	131	132	134	137	140	143	147	152	157	162	167	173	179	185	192	200
“ 40 to 45	133	134	136	139	142	146	150	155	160	165	170	175	180	186	194	203
“ 45 to 50	134	136	138	141	144	147	151	156	161	166	171	177	183	190	198	204
“ 50 to 55	134	136	138	141	145	149	153	158	163	167	172	177	182	188	194	201

The committee come to the conclusion that longevity depends largely upon build. The greater the variation from average of 5 feet, 7, 8, or 9 inches the greater the risk. The lighter the weight the greater the liability of death short of the expectancy from tuberculosis and nervous diseases. Overweights suffer from heart-disease and apoplexy. The table shows the constancy of weight-increase with age-increase. Dr. Moss considers underweights poor risks when over 20% below the limit, and overweights when over 25% above. In the discussion Dr. Warner observed:

In earlier years there were quite a number of persons who were 6 feet and 6 feet and 1 in. and 2 and 3 in., but that on the sheet on which were those above 45 and 50 years, scarcely a single one of these persons appeared. They either were so well fixed financially that they did not need life insurance or they were not in existence to insure. And those people who were 6 feet and above that who appeared on the sheets up to 30 years of age, the same proportion of them did not appear on the sheets after 30 years of age, and on to 40, 45 and 50. I arrived at the conclusion, then, that an increased height beyond 5 feet 10 in. is an increased hazard for some cause, which I cannot explain, except that they are not here to seek life insurance.

If it should become sufficiently certain that stature is such an important factor in longevity, the expectancy tables should evidently be revised. But whether this is done or the risks individually declined by the examiners, it is evident that life insurance is operating with natural selection to weed out the extremes. Whether one considers the alliance an unholy one will depend upon the "personal equation." The overweights and underweights, according to the fashion, might combine, syndicate their interests, and teach the insurance people a lesson. Even giants and pigmies have some rights.

The Treatment of Plague by Extirpation of the Infected Lymphatic Glands.—The plague has been decreasing slowly in Rio de Janeiro. From April to October there had been 492 cases with 248 deaths—a

mortality of not quite 50%. The Brazilian authorities seem to have combated the disease with intelligence and some degree of success. The latest news from Rio is that the plan has been adopted there of extirpating the lymphatic glands in cases of plague, on the theory that the infection takes place through the skin and thence by way of the lymph channels and the lymphatic glands. Dr. W. Havelburg, of the U. S. Marine-Hospital Service, has written an account of this treatment. The measure itself is, of course, very simple, consisting merely in the enucleation of the cervical, axillary, or inguinal glands, as the case may be. The theory is what attracts attention, and may be said to take a number of important things for granted. In the first place it is not clear by any means that the bacillus of plague always finds entrance into the body by way of the skin. But granting that it does the theory is about as follows: The germ settles in the lymphatic glands, develops and produces toxins. If a reactive inflammation, producing pus, occurs, the development of the bacilli is checked, and the plague is localized. If, however, this reactive inflammation is not sufficient, then the toxin and the bacilli enter the circulation and cause a general infection. According to this view, the glands act as protective ramparts; if the germs succeed in breaking through the ramparts, then the consequences are general and indeterminable. Therefore the plague has two periods of infection: (1) the local or glandular, (2) the general or systemic. The indication for treatment is to determine when the local period is still present, and promptly extirpate the glands. Evidently, this plan of treatment cannot be adopted in the pneumonic and intestinal types of plague. Dr. Havelburg claims that the results at Rio de Janeiro seem to have been favorable. The temperature is favorably influenced, and the therapeutic results are better. But his report contains few details by which we can judge of this treatment. It seems to us to be an exceedingly theoretic one, with small promise of practical results.

Insanity Among the Jews.—Although the Jews no longer constitute a nation they often exhibit certain racial qualities in common; but these tend gradually to disappear in the process of assimilation with the communities in which they reside. When, however, such assimilation does not take place, and the Jew, by choice or by force of circumstances, segregates himself, he will continue to exhibit peculiarities, as a result, in part of hereditary influences, in part of environmental conditions. There can be no doubt, also, that certain religious customs and perhaps the general moral status of the Jews are responsible for the lessened prevalence of certain diseases among them. Thus, syphilis, tuberculosis, alcoholism and crime are believed to be less common in general among Jews than among Gentiles. By reason of his history the Jew is on the other hand usually more neurotic than his neighbor, and insanity

appears to be more common among Jews than among others. Thus Beadles (*Journal of Medical Science*, October, 1900) in a study of 1,000 cases of insanity at the Colney Hatch Asylum noticed a great preponderance of general paralysis among Jewish males, over 21% of all male Jews admitted being subjects of that disease, while the proportion of cases of general paralysis among all males admitted to hospitals for the insane in England and Wales is 13%. No such disparity has been observed among Jewesses, although puerperal insanity was more common among them than among others—namely in 15% as compared with 6%. At the same time syphilis appears to be rather less than more common among Jews than among others; and drunkenness also is said to be less common among the poorer Jews than among others of the English lower classes; while sexual excesses are frequently assigned as a cause for insanity among Jews. As a result of the intensely emotional life of the Jews, the males are often neurotic, the females hysterical. It was found that insanity appears earlier in Jews of both sexes than in non-Jews, at 37 as compared with 43 years; and that likewise death occurs earlier, at 44 and 47 years for males and females respectively, as compared with 51 and 55 years. Relapse occurred twice as frequently in Jewish patients discharged from hospitals for the insane as in other patients. As has already been stated, the explanation for the peculiarities that the figures cited bring out is to be found in part in hereditary, in part in environmental influences. That this is so is indicated by the fact that over 80% of the Jewish patients or their parents were born abroad, and that many had suffered from impoverishment and privation.

Appendicitis with Undescended Cecum and Appendix.—C. A. Hamann (*Cleveland Medical Gazette*, October, 1900) calls attention to the fact that congenital anomalies of the cecum and appendix must be borne in mind in the consideration of obscure intraabdominal affections and cites the case of a patient who had suffered from pain in the right hypochondrium for 5 or 6 years. The pain was almost constant, though worse at intervals, and had disabled him from work for the last few months. There had never been any acute attacks resembling gallstone-colic or appendicitis or any other acute abdominal disease, nor was there a history of traumatism. There was localized tenderness, just below the costal border, at the outer edge of the right rectus muscle; the muscle was rigid. No tumor could be felt. It being impossible from the symptoms present to make a positive diagnosis, an exploratory incision was devised. Upon opening the abdomen in the semilunar line, over the point of tenderness, it was found that the caput coli looked directly upward, and appendix lay partly under the liver. The cecum was of the "second type" described by Treves, i.e., the appendix arose between 2 equal sacculi; it had a short mesentery. The appendix was 4½ inches long and had a mesentery throughout its entire length. About an inch from its base lay a soft cecal concretion, around which there was a shallow ulcer. The coats of the appendix were somewhat thickened, and presented the changes described by Deaver under the head of "chronic interstitial appendicitis." There were no adhesions. The patient was completely relieved of pain and tenderness and made an uneventful recovery. [G.C.C.H.]

Special Article.

FURTHER REMARKS ON THE BISECTION OF FEES, SURGICAL DRUMMERS AND DRUMMING SURGEONS.

By G. FRANK LYDSTON, M.D.,

Professor of the Surgery of the Genitourinary Organs and Syphilology, Medical Department of the Illinois State University; Professor of Surgery, Chicago Clinical School.

IN THE PHILADELPHIA MEDICAL JOURNAL, issue of November, 1899, I published an article entitled "The Surgical Commission Man and Surgical Canvassing." In this article I offered positive proof that with a large proportion of men occupying high places, the practice of medicine and surgery is not a profession, but a trade—and a pretty low trade at that. Since writing this article, I have discovered that conditions are even worse than I thought. Not only do surgeons of prominence solicit "surgical trade," while general practitioners auction off their surgical cases to the highest bidder, but public apologists for the nefarious custom have appeared upon the scene. Upon specious and sophistical pretexts, certain medical journals have either tacitly sanctioned or openly commended the practice. One drumming surgeon has gone so far as to put in a piteous plea for patronage on a commission basis, under the guise of excusing the poor country doctor. This article has appeared as "original" matter in four or five medical journals. I have received many letters upon the subject, most of which, I am happy to state, endorse the position I took in my previous article. Anonymous abuse I have received not a little of—which latter is confirmation of the opinion I have expressed of men of the commission kidney:

The time seems ripe for a further communication on "surgical drumming."

The arguments advanced by the champions of the struggling general practitioner are based upon the same business principle that actuates the pickpocket and others of his ilk. I have been asked by many if I did not think the general practitioner who brings a case to the city specialist should be paid for his services. Others, again, have intimated that my former article would tend to increase the evil, rather than to repress it.

I have used the expression, "drumming surgeons." Exception may be taken to this by many, but, can there be any logical opposition to this nomenclature? Laying the code question aside altogether, there is a standard of professional conduct that is tacitly accepted by all reputable men in the profession. This standard, while difficult of crystallization, is an unvarying one so far as its main principles are concerned.

As I understand the matter, a "drumming doctor" is a man who has paid agents upon whom he depends wholly or in part for his "business." The medical drummer is the man who takes his business to him. The drumming doctor and the doctor's drummer of Hot Springs, Arkansas, constitute the most definite type of their class. Let us see how they are regarded by the profession.

The reputable men of Hot Springs have an organization in affiliation with the American Medical Association, which rigidly excludes the drumming doctor as unfit for association with decent medical men. Should a member be caught red-handed in drumming he is forthwith expelled. Be it remarked that the drumming doctor of Hot Springs pays 50% commission. The reputable physicians of Hot Springs refuse to consult with drumming doctors on the ground that they are disreputables and quacks. The profession in general throughout the country condemns the Hot Springs drummer and his principles—and his lack of principles—and, so far as may be, prevents any of its patients who chance to go to the Springs from falling into their hands on the ground that they are wolves and quacks. Wherein lies the difference between the drumming quack of Hot Springs and the so-called reputables who are giving medical agents a 50% commission for such work as may be brought to them? Now I am going to do the Hot Springs drumming doctor the justice that is denied him. He is not to take it as a compliment, for I do not intend it as such, but he is, in my opinion, the ethical and moral superior of the "reputable" (sic)

commission man. He is no more nor less than he pretends to be. He might well quote Omar Khayyam:

'A Shaikh beheld a harlot, and, quoth he,
'You seem a slave to drink and lechery.'
And she made answer, 'What I seem I am,
But, master, are you all you seem to be?'

He is a "drumming doctor," no more, no less. He is not a hypocrite. He does not belong to the American Medical Association, nor to societies in affiliation with it. He pretends to be no more than he is. He has this in his favor, viz., it is possible for those who believe not as he believes, to hold aloof from him. He prostitutes the profession not at all, for he is not a part of it. He prostitutes himself not at all, for he has no ethics, and is a mere business man, as he would say, "out for the stuff." He does not prostitute his agents, for they are also business men and have no ethics to violate. More than all, they are not medical men.

The commission man who carries on his trade beneath the cloak of professional ethics, who perhaps belongs to the American Medical Association or numerous societies in affiliation with it, is an arch hypocrite. He is a wolf in a wool jacket, he prostitutes not only the noble profession of which he pretends to be a part; he prostitutes not only himself, but he also prostitutes the medical man whom he employs as his agent. He is, moreover, an advertiser of the most flagrant kind—for what is the employment of paid agents but most effective mercantile advertising? He by no means occupies so high a plane of respectability as does the man who walks up to the cashier's window at the newspaper office and pays for his weekly advertising. This fellow does the profession no harm, and the public is welcome to him.

Apropos of drumming, I know of numerous instances in which surgeons of repute are in the habit of approaching general practitioners in this manner:

"By the way, Dr. B., who is doing your surgical work?"

"Why, I have been in the habit of sending most of it to Dr. J."

"Well, do you get anything out of it?"

"No, I have never thought of asking for anything."

"Well, now, you ought to get something out of your cases. If you'll send your work to me I'll divide fees with you."

This is the substance of a recent experience of one of my medical friends, whom I am proud to know as being immune to such contagion. In my previous contribution I mentioned one gentleman who volunteered to have his assistant at the train to meet any patients that might be consigned to him at 50% commission.

The extent of the commission evil is simply appalling. A very large proportion of Chicago surgeons are practising it. Those in other large cities are as bad, or worse. The percentage shown by my investigations—already published in this journal—is a very low estimate. Some of the men who answered the letter from a supposed medical drummer, in a tone that suggested an impeccable standard of professional conduct, are in the commission business, but the letter which they received was so broadly businesslike that the recipients were suspicious. Others, against whom I have incontrovertible evidence, "smelled a redent," and did not answer the letter at all. The letter was purposely made very broad, to guard against the possibility of any of the commission men claiming that they did not know what the writer of the letter meant. The man who answered that letter must needs be committed absolutely. It is worthy of note that men whose answer repudiated the commission business, yet are continuously engaged in deliberately doing that which they know and acknowledge to be morally wrong.

It might be edifying to the general practitioner who reverences the college men to know that many of them are, in the commission business. I'd rather not say how many of my own colleagues, like Barkis, are "willin'."

Now, I desire to submit certain propositions, which I am willing, aye, anxious to debate in the columns of this journal. Indeed, I hope my commission friends will come out from their hiding place beneath the frazzled skirts of that good old witch-wife, "Granny Code," and, nailing their colors to the mast, have it out with me. These propositions are as follows:

1. There is no difference between the so-called reputable surgeon who pays commissions (or the man who works for him on commission), and the Hot Springs drumming quacks, that is not in favor of the latter.

2. The commission man is an advertiser on a lower plane than the quack advertiser in the newspapers.

3. The commission man does not dare come out in open meeting and advocate the practice as such. He is in most instances a subscriber to the code. He is a hypocrite.

4. He is a menace to the general prosperity and respectability of the profession. He is degrading himself and his profession every day he lives.

5. He is as dishonest as a man can be without violating statutory law. This requires a word of explanation: He is dishonest in his treatment of the patient by virtue of a charge which is supposed to be for his own services alone, whereas it embraces a commission for the medical steerer who has brought the case. Neither the operator nor his drummer dare present the details of the transaction to the patient, hence I cannot see the difference in the matter of "shadiness" between this and other transactions of a so-called "business" nature that will not bear the light of day. I maintain that any dealings of a monetary character between the surgeon, the man who brings the case to him, and the patient, which will not bear presentation to the latter in black and white, is dishonest.

The rank and flagrant dishonesty of the commission surgeon is most thoroughly established by the following indubitable facts:

1. He divides with the man who demands a division.

2. He divides with him whose patronage he can get in no other way.

3. He does not divide with those who send him the bulk of his work. If he is justified in paying commissions to one person he should pay them to all. If he is honest in paying any commissions whatever, he is a swindler if he does not divide with every one, lay or professional, who sends him a case. He does not so divide, hence he may take his choice of the two horns of the dilemma. I am not inclined to mince words. I herewith assert that the commission surgeon is of necessity a swindler. I do not think he robs himself. He robs his patients, and all of his lay and professional friends who send him cases, yet to whom he pays no commissions.

4. The practice of commission paying is even now leading to criminal collusion on the part of the surgeon and his drummer. Inoperable cases are being *operated at* for a divided fee. Cases in which operation is unnecessary are being operated on a fee bi-section basis. Dishonest diagnosis followed by dishonest operations are being made. There's nothing so "thick as two thieves," and as the chief malefactor—the commission surgeon—and his "pal"—the drumming doctor—are in duty bound to stand by each other, the poor patient is of necessity playing the role of football. Do I overdraw? No; I can prove that cases of an inoperable character are being auctioned off to the highest bidder. I can also prove that the drumming doctor with any case that he wants "operated," is never allowed to leave our great medical centers unsatisfied.

5. Having degraded himself by the commission business, the fee bisector has gone further and formed an offensive and defensive alliance with out-and-out quacks. I know of one gentleman who makes periodic excursions to a neighboring small town to operate for an advertising quack. He operates upon every patient that the quack has in readiness. He worries not over diagnoses. The quack has advised operation, the patient has consented to it, the fee is to be divided and—what would you more?

6. The general practitioner who refers a case to a specialist for operation is supposed to be actuated by a desire to further the best interests of his patient. Is it this that actuates him in demanding a commission for his patronage? In justice to the general practitioner who is in the drumming business, I should say that it is my belief that the first advances on a commission basis were made by the specialists themselves. The general practitioner is intrinsically decent. Most of those who are drumming have been corrupted by the specialists.

The drumming practitioner dare not let his patient know of the financial arrangement he makes with his principal. Once let the public get an inkling of the business and it will demand a better knowledge of the practitioner's character than it now possesses before operations will be consented to. Let the patient and his family discover the deal which some family physicians are making with the commission men and

there'll be a change of doctors very quickly. The commission business is shady, my brother, and you dare not let your patient find you out. Come now, do you? Will you, my brethren, who have occasionally asked me how much I would give you if you would turn certain cases over to me for operation, permit me to ask your patients what they think about your methods? It will be no trouble to me, I assure you. I have names and dates a' plenty. Besides, I am ever ready to oblige. The patient would open his heart to me, you know, just as he has opened his pocket to you and your principal in the "surgical trade."

The drumming doctor does not worry much about who will be likely to render the patient the best service. All he wants to know is, what surgeon asks the fewest questions of diagnostic import and pays the biggest commission. The commission man has put up a very pathetic plea in behalf of the drumming doctor. The burden of this plea has been, "The poor fellow ought to have something for his trouble."

This is a plea that fools nobody. The commission surgeon has about as much philanthropy in his composition as a shark, and less warm, red blood than a clam. But the plea eounds well and brings him business. I believe the general practitioner to be overworked and underpaid. But does this justify him in dishonest practices? Is the argument that he needs money any more cogent here than in its application to out-and-out quackery, the abortion business, or even to picking pockets? I grant that the general practitioner should be paid for everything he does; but should he be paid money he does not earn? Should he be paid for something he has not been employed to do? Should he receive money from a transaction which, if known to his patients, would lose for him the respect, confidence and esteem, not only of the patient, but of his entire clientele?

It is often said that the doctor who brings the case has never received any fees from it. Well, if not, why not? If he is not a sufficiently good business man to get such fees as may be due him from the patient, should he hold the specialist responsible and demand that he collect them for him surreptitiously? Or, granting that the surgeon charges no more than is just and fair for his operation—and anything within the range of the patient's financial capacity is just and fair, due regard being paid to the seriousness and responsibility of the case—should the general practitioner expect the operator to pay him for real or imaginary services rendered the patient? By no means. The practitioner often accompanies the case to the medical center, it is true, and guides it directly to the office or hospital of the specialist. This has been urged as a special plea for his compensation on the part of the specialist. But let us inquire into this bit of sophistry a little, especially as to the reasons actuating the practitioner who accompanies the case. In many instances the practitioner is asked to accompany the patient by the patient or by his friends. In such an event the doctor who does not give the people employing him due and proper notice that he is not traveling for his health, is a fool. Not only does he lose his time and services, but the family will have little respect for him in future, and their opinions will permeate the place in which that doctor practices like a pernicious and deadly miasma. It will blight his hopes of ever obtaining a competence in that community. Make the people pay you, my brother, and pay you well. Surely you do not think the specialist ought to pay the bill. In not a few instances the practitioner accompanies his patient for purely politic motives. The family is an influential one, and he wishes to keep or make himself "solid" with it. Perchance he has had a steady income from that family for years. Actuated by this motive he accompanies his patient to the city. Should either specialist or patient pay for this? I believe the patient should pay; but if the practitioner has accompanied the case out of alleged sheer good-will, I fail to see that he should expect compensation from anybody. He is a fool who makes such an arrangement, but having made it he should stand by it. Supposing the patient should learn that his generous and self-sacrificing doctor got a "divvy" for bringing him to the specialist, what a precious row there'd be. The doctor thus caught would best change locations, and stand not upon the order of his going.

If the doctor is under no obligation to the patient—he or she being a new one—there is no earthly excuse for his going to the city with the case unless he is employed by the patient to go as a matter of pure business. In some instances the

general practitioner accompanies his patient for another reason. The case has been upon his hands for a long time. If he has not received pay for his services, he should have done so; it is his own fault if he has not. The case is a puzzling one and he is anxious to see it through. "Well," he then says to himself, "I will see what Prof. X. says about it; I will watch the operation, so that I may know what to do and how to do it next time." Should the patient pay for this, unless with a clear understanding that he is expected to pay for the doctor's company? Should the specialist pay for it?

The thing that puzzles me most in the commission practice, is how the specialist and the general practitioner figure out their standing upon the same operative and diagnostic plane. The practitioner would not take the case to the specialist if he could help it. He cannot handle it and so is perforce compelled to seek higher authority. Having sought it, he attempts to put himself on the same plane with that authority by demanding an equal division of the fee—a fee earned by a man who understands and skilfully handles a case in the presence of which the general practitioner is absolutely helpless—a fee that the latter not only does not earn but could by no possibility earn, as he himself admits.

A point to be remembered is this: The general practitioner may have enjoyed a lucrative practice in the family of which a given patient is a member, for many years. The surgeon specialist has never competed with him in any respect. He has had a monopoly of the practice in that particular family—why should he object to the surgeon having a monopoly in the occasional case which he himself is not competent to manage? "Render unto Cæsar those things which are Cæsar's." In order to obtain preeminence as a specialist one must sacrifice a goodly portion of the field of practice. He is entitled to his own, no more, no less. If he does enter into competition with the general practitioner, then the latter should not refer cases to him. The specialist, too, should "render unto Cæsar those things which are Cæsar's." Get your fees, my brother overworked, and let them be good ones, but do not try to compensate yourself for your own lack of business ability by participating in any transaction which is so shady that, if you were found out, it would ruin you.

This objection has been urged to my ventilating the "drumming business": "You only serve to advertise those fellows and make the practice more prevalent than ever." Well, there's something in that, I admit. But, brethren, *I wish to advertise them. I wish to compel them to bisect their incomes by dividing with all their patrons who refer cases to them.* If they divide with one, why not with all? Because they are dishonest in two directions. They are not as square as the professional crook who believes in "honor among thieves." When I am ready I am going to advertise them in another way that will make their hair curl—unless, mayhap, they are bald.

Is there any basis of copartnership upon which the general practitioner and the specialist can possibly meet? Yes, there is:

1. A general practitioner and a surgeon may form a copartnership out and out, and announce the fact, presenting joint bills for services.

2. The specialist may present a joint bill which openly claims a fee for combined services, the general practitioner and surgeon each receiving his fair and just proportion of the fee—adjusted according to the services actually rendered by each.

3. The general practitioner may conduct all the financial negotiations with the patient, call a surgeon in to operate and pay him whatever sum is agreed upon between the two physicians. Here the general practitioner presents a bill which is understood by the patient to be a bill for joint services. If the patient is satisfied with the total amount he is not likely to concern himself with the arrangement that his physician has made with the operator. If the surgeon is satisfied with his own fee, it is a matter that concerns nobody else.

4. There are cases in which the general practitioner may render honest and competent assistance to the surgeon. Here a joint bill should be rendered.

If there are any other ways in which the surgeon and the physician can cooperate financially, I should be glad to know of it.

I hope that the question of whether we are practising a profession or a trade may be settled in the near future. At present the matter is somewhat confusing. In Chicago things are very complex. It is an unwritten law that a reputable physician does not advertise in the newspapers. Several

reputable men may do so, however, without stain. A certain postgraduate school has "an ad" in one of the papers containing the names of four or five of the faculty. In this the public is informed not only that they are great doctors, but are engaged in teaching "practitioners of medicine" only. I wonder what part of the school's clientele is reached in this way. I wonder, moreover, how the other members of the faculty like to pay their *pro rata* for that ad. Mind you, the men aforesaid are men of great ability, and personal friends of mine for whom I have great admiration, but!—

There are physicians in Chicago who are supposed to be reputable, yet demand a division of the spoils from the undertakers to whom they refer "cases" or into whose hands their "cases" fall. And the instances of this ghoulish practice are not isolated ones either, nor are the doctor-ghouls so very obscure in some cases.

Certain hospitals have an arrangement for a "divvy" with particular undertakers. The family of the deceased must "hustle" if it would have anything to say as to the disposition of the remains so far as the selection of an undertaker is concerned. The ice melts pretty fast around some hospital corpses, and one would be justified in suspecting that the remains had been put on pretty hot in some cases.

The latest thing in "divvies" is the insurance frauds in which two supposedly reputable practitioners have been detected. This is only a little worse than paid testimonials for new drugs.

Apropos of testimonials, when a practitioner discovers a remedy that cures 100 cases of gonorrhea in from 4 to 5 days to 3 weeks, and within six months after his report has appeared has abandoned the drug for a rival preparation, there's a "nigger in the fence." The man who discovers such a remedy can live in a gold house.

Pregnancy and Heart Disease.—G. G. Sears (*St. Paul Medical Journal*, November, 1900) details a series of 15 cases in patients who were 19 times pregnant under his observation, which were successfully gone through with after cardiac lesion was acquired. The course of these cardiac cases under the influence of repeated pregnancies is not necessarily progressively downward, since a pregnancy with severe cardiac symptoms may be followed by one in which they are scarcely noticeable, yet the net result in most instances has been a decidedly weakened heart. Six patients had mitral stenosis, 2 mitral regurgitation, 1 aortic regurgitation, 3 both mitral regurgitation and stenosis, 3 combined aortic and mitral lesions. Two patients died, one with mitral stenosis and one with a double mitral lesion. In 5 cases abortion was induced, 2 patients having mitral stenosis, 2 combined mitral and aortic lesions, 1 mitral regurgitation and stenosis. There seems indicated the necessity of inducing abortion, if marked symptoms of failing compensation develop before the third month and do not respond to treatment, and on its probable necessity if they appear between the third and sixth month. The ease with which patients passed through an abortion brought on before the fifth month is a decided argument for its early performance, before the mechanical difficulties from the increased size of the child have become too great. He has never seen reason for reproach for having advised an abortion in any case, while he has twice had reason to regret that an opinion was sought too late for premature delivery to be effective. [O.C.C.U.]

Fatal Lead Poisoning.—Ruines (*The Canadian Practitioner and Review*, November, 1900) reports 2 cases of fatal lead poisoning occurring in children aged respectively 5 years and 9 months and 2 years and 8 months. In addition to the signs and symptoms ordinarily given in textbooks there was a well-marked dark-blue circle about the anus. The condition resembled basilar meningitis very closely. The younger of the 2 children lived about 3 weeks after the onset of the attack, and the elder about 1 week. The convulsions in each case were very numerous. Attacks of vomiting, constipation, contracted abdomen, offensive breath, dilated pupils, abdominal pain, and loss of reflexes were noted. The urine contained 1 milligram of lead to the ounce. The poisoning was caused by the inhalation of the fumes from the burning staves of a barrel which had previously contained white lead. The mother was also poisoned and suffered from lead colic and other classic symptoms of lead poisoning. An infant at the breast was not poisoned. [A.B.C.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended December 15, 1900:

Monday, December 10—College of Physicians, Section on Medicine.

Tuesday, December 11—Pediatric Society.

Wednesday, December 12—County Medical Society.

Thursday, December 13—Pathological Society.

Sneak thieves' latest scheme is to enter a physician's waiting room under pretence of wanting a consultation, and appropriating overcoats and other personal belongings of those who entered the consulting room.

Impure Milk.—The Berks County Dairymen's Association at its recent annual meeting decided to call the attention of the Food Inspector to alleged adulterated milk sold in Reading by some of the 100 dealers outside the Association who serve routes in that city.

Hospitals for Epileptics and the Tuberculous.—At a recent meeting of the State Board of Charities in Pittsburgh the question of State institutions for the care of epileptics and tuberculous individuals was discussed. All members were in favor of the project, and a recommendation to the next legislature for the establishment of such hospitals may result.

Medical Inspectors.—A resolution recommending that the medical inspectors of schools be paid a salary of \$500 each for their services from September to May inclusive was adopted at a recent meeting of the Committee on Medical Inspection of the Public Education Association. The committee suggested that the corps of visiting physicians should number 200.

Franklin County Medical Society.—At the regular meeting at Chambersburg, October 16, 1900, the following officers were elected for the year 1901: President, Dr. Jos. K. Snively; vice-presidents, Drs. A. W. Thrush and A. D. Dalby; recording secretary, Dr. J. J. Coffman; corresponding secretary, Dr. H. Clay Devilbiss; treasurer, Dr. D. Mac-lay; censor 1901 to 1903, Dr. A. H. Strickler.

Vital statistics of Philadelphia for the week ended, December 1, 1900:

	CASES.	DEATHS.
Total mortality		446
Inflammation of appendix 1, bladder 1, brain 5, bronchi 12, kidneys 13, lungs 63, pericardium 1, peritoneum 11, pleura 1, stomach and bowels 18		126
Lungs—tuberculosis of 58, edema of 2, abscess of 1		61
Heart—diseases of 38, fatty degeneration of 2, neuralgia of 2		42
Uremia 19, diabetes 5, Bright's disease 6		30
Marasmus 8, inanition 11, debility 3		22
Apoplexy 13, paralysis 7		20
Old age		20
Carcinoma of breast 4, face 1, larynx 1, pelvis 1, stomach 7, uterus 2, bladder 1, sarcoma of jaw 1, stomach 1		19
Casualties		16
Diphtheria	105	14
Brain—congestion of 3, softening of 2, hemorrhage of 1		6
Typhoid fever	42	6
Convulsions 5, puerperal 1		6
Alcoholism		6
Liver—diseases of 1, cirrhosis of 4		5
Membranous croup		4
Scarlet fever	39	4
Suicide—hanging 2, Paris green 1, shooting 1		4
Burns and scalds		3
Cerebrospinal meningitis		3
Dropsy		3
Obstruction of the bowels		3
Aneurysm of aorta 2, asthma 2, atheroma 1, childbirth 2, cyanosis 2, diarrhea 2, drowned 1, epilepsy 1, erysipelas 1, jaundice 2, locomotor ataxia 1, rheumatism 1, arterial sclerosis 1, surgical shock 1, septicemia 1, syphilis 1		1

Milk from Tuberculous Cows.—The State Inspector last week condemned to death as tuberculous 95 cows of Reedhurst stock farm. They have been appraised at \$1,300, which the State will have to pay. The milk from this herd brought high prices on account of its supposed excellence.

NEW YORK.

The Medical Society of the State of New York will hold its ninety-fifth annual session in Albany January 29, 30, 31, 1901.

Bequests to Hospitals.—R. G. Dun bequeaths to his will filed recently to the Presbyterian Hospital, St. Luke's Hospital, Mount Sinai Hospital and the New York Institution for the Instruction of Deaf and Dumb \$5000 each.

Gift to the Woman's Hospital.—At a recent meeting of the Woman's Hospital in the State of New York it was announced that Mrs. Frederick F. Thompson had offered to build a nurses' home in connection with the hospital, the home to cost from \$100,000 to \$150,000 and to be erected on the hospital grounds. This gift is in addition to \$55,000 given early in the year.

Cost of Public Baths.—Before the Tenement-House Commission recently, an estimate was given of the expense of running the People's Bath at Center Market. Last year the cost was a little over \$5,000, and with a fee of 5 cents for each bather for use of soap and towel, paid a slight profit over running expenses, though 6,000 free baths were given. This is only $\frac{1}{3}$ smaller capacity than the Rivingtonstreet bath, for which an appropriation of \$51,000 has been asked of the city for maintaining it one year.

A West-Side Plague Spot.—A meeting was recently called at St. Michael's parish-house, New York City, to hear the report of experts on the conditions of life in a block on the West Side. It has been called the plague spot of the West Side. In 1897 this spot contained 3,580 persons living in 2,639 rooms, of which only 1,198 had windows on the outer air. There was not a single bath-tub, except in 2 houses where 6 families were provided with a private bath, leaving more than 800 families unprovided for. Of these 89 families had hot and cold water, the remainder cold water only. It is reported that the general feeling is that the board of health has not done its duty by this block.

NEW ENGLAND.

Salem Sanitarium.—The main building at Lowell Island in Salem Harbor, Mass., used for a children's sanitarium, will be torn down and a more convenient structure erected on the same site.

The Dickinson Hospital at Northampton, whose trustees appealed for aid in their last annual report, has had a gift sufficient to build the needed annex at a cost between \$15,000 and \$20,000. The building is to be a memorial.

The new Willard Hospital, of Bedford, Mass., established for the care and treatment of chronic alcoholics, reports great encouragement in the work. Improvements involving an outlay of \$5,000 are contemplated. The Willard Hospital is named in honor of Miss Frances Willard, who did so much in her short life for purity and temperance.

Christian Science.—A recent report of a committee read before the Newton, Mass., School Board contains the following clause: "Now that there is said to be an increasing number of people called christian scientists, who deny the existence of disease, it seems to us that some additional precaution should be taken against this danger. We are informed that the Newton Educational Association is seriously considering this matter, and has called upon the physicians of the city for advice."

CHICAGO AND WESTERN STATES.

Chicago Wesley Hospital.—Many generous contributions have been made in that city for its erection, amounting to \$140,000.

St. Edward's Free Hospital is the name of a new institution to be erected at New Albany, Ind., by the St. Mary's Catholic Church.

Oleomargarine Dealer Fined.—John R. Roney, of Chicago, was recently fined \$1,000 and costs for selling oleomargarine without having paid a wholesale tax and without marking his goods.

SOUTHERN STATES.

Anilin Dye in Sausage.—Two dealers were fined recently in the Baltimore Criminal Court for selling Frankfurt sausage colored with anilin dye, which the jury decided was unwholesome.

Richmond (Va.) News.—Dr. John F. Winn, Superintendent of Dispensaries for Lying-in Women, in connection with the University College of Medicine, Richmond, Va., has just handed to the faculty of that institution his report for the past 12 months. In all, there were 281 cases of delivery in the out-door department. This number includes full-term deliveries and miscarriages, embracing exceptional opportunities for the students to assist in the work.—At a recent meeting of the Academy of Medicine steps were taken by the body to vigorously prosecute all illegal practitioners and concerns engaged in the treatment of diseases. This includes the cancer-curers, rupture-curers, osteopaths, viarists, etc.. A strong committee was appointed to look up evidence in order to aid the Commonwealth's attorney and, if necessary, appear before the Grand Jury to maintain the principle.

CANADA.

A Medical Defence Union.—At a recent meeting of the St. Francis District Medical Association, the medical men of the eastern townships of Quebec took steps to form a medical defence union. Copies of the rules will be at once sent to all medical men in that district for their signatures, when the organization will seek the endorsement of the Canadian Medical Association. The association also decided to accept and adopt the Ontario code of ethics. Hereafter the society will meet every 2 months.

MISCELLANY.

Pan-American Medical Congress.—A committee of the Pan-American Medical Congress met at Washington, D. C., December 4, to consider the advisability of postponing the meeting of the proposed Congress at Havana, owing to the prevalence of yellow fever there. It was decided to hold the convention in that city from February 5 to 9, instead of December 26-29.

Obituary.—ROMAINE J. CURTISS, of Joliet, Ill., November 20, aged 60.—RUFUS P. LINCOLN, of New York City, November 27, aged 59.—GEORGE HEUSSY, of Seattle, Wash., aged 54.—JOHN S. HOLSTEIN, of Florence, La., November 19, aged 28.—A. S. JORDAN, of Riegelsville, Pa., November 23, aged 61.—WILLIAM F. MAHNEKE, of Pittsburg, Pa., November 18, aged 50.—EDWIN PATBURY, of Washington, November 20.—JOHN SWAN, of Westbrook, Me., November 18, aged 60.—THEODORE J. YOUNG, of Titusville, Pa., November 22, aged 68.—EDGAR VOELCKER, of San Antonio, Tex., November 24, aged 26.—J. W. BROCK, of Leavenworth, Kan., November 26.—LUDGER MARK FINNEY, of New Orleans, November 30, aged 38.—FRANCIS M. CLARK, of Shamokin, November 30.

Changes in the Medical Corps of the U. S. Army, for the 2 weeks ended December 1, 1900:

HARVEY, Major PHILIP F., surgeon, will proceed to Zamboanga, Mindanao, reporting to the commanding general, department of Mindanao and Jolo, for duty as chief surgeon of that department, relieving Major Richard W. Johnson, surgeon.
JOHNSON, Major RICHARD W., surgeon, will proceed to Ilo Ilo, Panay, reporting to the commanding general, department of the Visayas, for assignment to duty.
EWING, Major CHARLES B., surgeon, is relieved from duty in the department of Northern Luzon, and will report to the commanding officer, Santa Mesa Hospital, for duty.
MATHEWS, Captain GEORGE W., assistant surgeon, is relieved from duty in the department of Northern Luzon, and will report to the provost marshal general, Manila, P. I., for assignment to duty.
WOLF, EDWIN P., acting assistant surgeon, is granted leave of absence for 25 days with permission to leave the limits of the division of Cuba.
HAYARD, Major VALERY, surgeon, is granted leave of absence for 1 month, with permission to go beyond the limits of the division of Cuba.
FRICK, Captain ELLIOT B., assistant surgeon, will report to the chief surgeon of the department of Porto Rico for duty as attending surgeon at department headquarters, vice Major P. R. Egan, surgeon, relieved.

EGAN, Major P. R., surgeon, is relieved from duty as attending surgeon, department headquarters, department of Porto Rico.

MACCLERY, HUGH H., hospital steward, will report at the medical supply depot, San Juan, P. R., for temporary duty.

EMERSON, HERBERT, hospital steward, U. S. Army, will report at the medical supply depot, San Juan, P. R., for duty.

KUHN, CHARLES F., acting assistant surgeon, is relieved from duty on the Army transport "Lawton," and is assigned to duty with troops on the Army transport "Sheridan," to sail for the Philippines about November 16. Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

DOUGLAS, GEORGE C., hospital steward, Army General Hospital, Washington Barracks, is transferred to Fort Monroe, for duty.

HESS, First Lieutenant LOUIS T., leave of absence is extended 1 month.

SHORES, ERWIN I., acting assistant surgeon, orders of November 13 are amended so as to direct that upon being relieved from duty at Fort Caswell by Acting Assistant Surgeon James H. Hepburn he will proceed to his home, West Bridgewater, Mass, and report by letter to the Surgeon-General of the Army for annulment of contract.

HEPBURN, JAMES H., acting assistant surgeon, is relieved from duty at the U. S. general hospital, Fort Bayard, and will proceed to Fort Apache for duty.

WEBER, First Lieutenant HENRY A., assistant surgeon, is granted leave of absence for 1 month, with permission to leave the limits of the division of Cuba, and to apply for an extension of leave for 1 month.

THOMASON, Major HENRY D., surgeon, is granted extension of leave of absence to include December 31.

THOMASON, Major HENRY D., surgeon, is honorably discharged from the service of the United States, to take effect December 31.

TRUEHOLTZ, CLARENCE A., acting assistant surgeon, is relieved from duty in the department of California, and will proceed, via Seattle, Wash., and Skagway, to Fort Egbert, Alaska, and report to the commanding officer of that post for duty.

KIERULFF, H. NEWTON, acting assistant surgeon, now at Seattle, Wash., is relieved from further duty in the department of Alaska, and will proceed to San Francisco, Cal., and report by letter to the Surgeon-General of the Army for annulment of contract.

WHITTINGTON, WILLIAM L., acting assistant surgeon, will proceed from St. Joseph, Mo., to San Francisco, Cal., and report to the commanding general, department of California, for assignment to temporary duty en route to the Philippine Islands, and upon arrival at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

KUCH, HERMAN, hospital steward, chief surgeon's office, division of the Philippines, Manila, P. I., will, when able to travel, be sent to the Army general hospital, Presidio, for duty.

GRAHAM, GEORGE, hospital steward, (appointed November 19) now at the Army general hospital, Presidio, will report for transportation to Manila, P. I., for assignment to duty.

DOHLE, MAX, hospital steward (appointed November 19) now at West Point, N. Y., is assigned to duty at his present station.

POTTER, Major SAMUEL O. L., surgeon, is granted leave of absence, on surgeon's certificate, until December 1.

BANTA, WILLIAM P., acting assistant surgeon, is granted leave of absence, on surgeon's certificate, for 1 month.

FRY, CHARLES W., acting assistant surgeon, will proceed to his home, Huntington, Ind., where he will report by letter to the Surgeon-General of the Army for annulment of contract.

FITZSIMMONS, ALBERT P., acting assistant surgeon, will proceed to his home, Tecumseh, Neb., where he will report by letter to the Surgeon-General of the Army for annulment of contract.

HOFF, Major JOHN VAN R., surgeon, is granted leave of absence for 1 month, with permission to apply for an extension of 10 days.

STOCKARD, JAMES K., acting assistant surgeon, is granted leave of absence until December 14.

MCCALLUM, F., acting assistant surgeon, is granted leave of absence until December 14.

TABRY, First Lieutenant ALBERT E., assistant surgeon, department of Cuba, is relieved from duty at Columbia Barracks, and assigned to Rowell Barracks, relieving Acting Assistant Surgeon H. M. James.

JAMES H. M., acting assistant surgeon, department of Cuba, will proceed to Cabana Barracks for duty.

BISPHAM, First Lieutenant W. M., assistant surgeon, department of Cuba, is relieved from further duty at Cabana Barracks, and will proceed to Columbia Barracks for duty.

GEDDINGS, First Lieutenant E. F., assistant surgeon, department of Cuba, is relieved from further duty at Santiago de Cuba, and will report at Morro Castle, Santiago, for duty as post surgeon.

SUMNER, First Lieutenant IAA A., assistant surgeon, is detailed as acting chief surgeon of the district of Santiago, Cuba.

ALLEN, FREEMAN, acting assistant surgeon, is relieved from further duty at Quemados, Cuba, and will report at Columbia Barracks, Cuba, for duty.

STONE, RANDALL C., acting assistant surgeon, will report for duty with troops on the transport "Meade" during the voyage of that vessel to the Philippine Islands, to sail about December 1. Upon arrival at Manila he will report to the commanding general, department of the Philippines, for instructions.

TRUEHOLTZ, CLARENCE A., acting assistant surgeon, is relieved from further duty in the department of California, and will proceed via Seattle and Skagway, to Fort Egbert, Alaska, for duty.

COOK, ROBERT P., acting assistant surgeon, is relieved from duty at Columbia Barracks, Cuba, and will report to Major Walter Reed, surgeon, president of the board for the investigation of infectious diseases in Cuba, for temporary duty.

BUSHNELL, Major GEORGE E., surgeon, is granted leave of absence, on surgeon's certificate, for 3 months.

POTTER, Major SAMUEL O. L., surgeon, having tendered his resignation, is honorably discharged from the service, to take effect December 1.

HOFF, Major JOHN VAN R., surgeon, is relieved from further duty in the department of the Lakes, and upon the expiration of the leave of absence granted him November 19 will report to the Surgeon-General of the Army for duty in his office.

BUSHNELL, Major GEORGE E., surgeon, is relieved from duty in the office of the Surgeon-General of the Army.

KIERULFF, NEWTON H., acting assistant surgeon, now at Vancouver Barracks, is relieved from further duty in the department of Alaska and will proceed to Seattle, Wash., and report on the transport "Kintuck" for duty as surgeon on that transport.

FLETCHER, JR., RICHARD M., acting assistant surgeon, leave of absence for 7 days is extended 23 days, with permission to apply for a further extension of 1 month.

HAY, Second Lieutenant WILLIAM RIDGELY, recently appointed, with rank from November 5, 1900, will proceed to Governors Island and report in person to the commanding general, department of the East for further orders.

Changes in the U. S. Marine-Hospital Service, for the 2 weeks ended November 29, 1900:

STONEA, J. B., passed assistant surgeon, is relieved from duty at Quebec, Can., and directed to proceed to Norfolk, Va., and assume temporary command of the service during the absence of the medical officer. November 20.

THOMAS, A. R., passed assistant surgeon, granted leave of absence for 4 days. November 3.

WILKES, H. W., passed assistant surgeon, granted leave of absence for 7 days from November 28.

COFER, L. E., assistant surgeon, directed to rejoin station at Los Angeles, Cal. November 17.

HOADY, W. C., assistant surgeon, granted extension of leave of absence for 2 weeks from November 3.

BAHAENBURG, L. P. H., assistant surgeon, relieved from duty at Liverpool, Eng., and directed to proceed to New York, N. Y., and report to Surgeon L. L. Williams, at Immigration Depot, for duty. November 16.

GIBSON, L. P., acting assistant surgeon, granted leave of absence for 10 days from November 13.

GOODMAN, F. S., hospital steward, granted leave of absence, for 30 days from December 19.

STONEA, J. B., passed assistant surgeon, bureau letter of November 20, directing Passed Assistant Surgeon Stoner to assume temporary command of the service at Norfolk, Va., amended, and directed to assume command of the service at Norfolk, relieving Passed Assistant Surgeon J. M. Eager. November 21.

EAGER, J. M., passed assistant surgeon, relieved from duty at the port of Norfolk, Va., to take effect November 30.

HORDY, W. C., assistant surgeon, granted leave of absence for 7 days, from November 25.

BILLING, W. C., assistant surgeon, to proceed to Clarksburg, W. Va., for special temporary duty. November 24.

THORNTON, F. J., assistant surgeon, granted leave of absence for 4 days. November 23.

MOORE, DUNLOP, assistant surgeon, to proceed to Port Townsend Quarantine, and report to medical officer in command, for duty. November 28.

EARLE, B. H., assistant surgeon, to proceed to Columbia River Quarantine, and report to medical officer in command, for duty. November 28.

LONG, J. D., assistant surgeon, to proceed to Baltimore, Md., for temporary duty during the absence of Assistant Surgeon Billings. November 24.

LYOYD, B. J., assistant surgeon, to proceed to San Francisco Quarantine, and report to medical officer in command for duty and assignment to quarters. November 28.

PIERCE, C. C., assistant surgeon, relieved from duty at the Tortugas Quarantine Station, and directed to proceed to Key West, Fla., and report to medical officer in command for temporary duty. November 27.

BAILEY, W. C., acting assistant surgeon, granted leave of absence for 3 weeks, from November 14.

BROWN, F. L., hospital steward, relieved from duty at Cape Charles Quarantine, and directed to proceed to Boston, Mass., and report to the medical officer in command, for duty and assignment to quarters. November 27.

PROMOTION.

Assistant Surgeon L. E. COFER commissioned as passed assistant surgeon, November 23.

Changes in the Medical Corps of the U. S. Navy, for the 2 weeks ended December 1, 1900.

DUNBAR, A. W., passed assistant surgeon, detached from the "Monongahela" and ordered to the "Vermont" for temporary duty with the crew of the "Wisconsin," and then to the Naval Hospital, Mare Island, Cal.

WILLIAMS, R. B., assistant surgeon, appointed assistant surgeon, from November 17, 1900.

KENNEDY, J. T., assistant surgeon, detached from the "Monocacy" and ordered to the Cavite Naval Station.
Burr, C. R., assistant surgeon, ordered to the "Monongahela." December 1.
McCLANAHAN, R. K., assistant surgeon, detached from the Navy Yard, Washington, and ordered to the "Indiana." December 1.
SPEAR, R., passed assistant surgeon, detached from the Naval Hospital, New York, and ordered to the "Buffalo." December 5.
WILLIAMS, R. B., assistant surgeon, ordered to duty at the Naval Hospital, New York. December 5.

Health-Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, for the week ended November 30, 1900.

Coffee Substitutes.—The year-book of the Department of Agriculture, soon to be issued, will contain an interesting article on coffee substitutes. Such substitutes as parched corn, wheat, peas, beans, and corncohs, as well as sweet potatoes cut into small pieces, dried and parched, have long been used. Chicory, a well-known substitute for coffee, is generally used, mixed with true coffee, and by many is thought to improve the flavor. Recently there has appeared on the market many coffee substitutes which claim to be made from cereals.

1.—Thorburn divides **varix** into three clinical classifications: 1. Developmental, that due to some hereditary weakness, as eczema, usually common in young males and apt to occur more frequently on the left side. 2. Obstructive, from pressure either systemic or outside, (tight garters) and more common in females. 3. Hyperemic, usually from some inflammatory disturbance, and appears as small stellate patches of dusky red streaks. But in all cases there seems to be some congenital defect with the venous system. [W.S.N.]

2.—Spencer reports among a group of **exceptional gastric** cases the case of a woman, who suddenly developed symptoms of acute gastritis, and a few months afterwards a fixed lump in the epigastrium; an exploratory incision revealed the pyloric third of the stomach-wall adherent, a small thick-walled abscess in the center of which was a fish bone 2½ inches long; the point had penetrated the left rectus muscle. [W.S.N.]

3.—Downie and Kennedy report **3 unusual cases of stricture of the esophagus in which gastrostomy was performed.** In the first, Frank's operation, 16 months afterwards the valve-like flap still held the contents of the stomach without the slightest leakage except when the patient coughed there was a slight ventral hernia. No cause could be found for the stricture, which was located opposite the second tracheal ring and was supposed to be syphilitic. The second case was of tuberculous origin, opposite the first tracheal ring with involvement of the larynx. Witzel's operation was performed to save suffering. [W.S.N.]

4.—Power **successfully removed an enlarged and displaced spleen**, which bears out the conclusions that recovery is to be looked for in most cases of splenectomy if the enlargement is not leukocythemic. [W.S.N.]

5.—Wright and Wylie report a case of a **tumor** in the left lumbar region of a child 2 months old; the lower border extended below the umbilicus, the upper above the costal margin. The abdomen had been swollen from birth. It appeared cystic and they tapped it, drawing off 19 ounces of albuminous fluid, and a week later the tumor had regained its former size. An operation was then decided upon and the cyst was found to occupy the lesser peritoneal cavity with adhesions to the walls and no pedicle. The child lived for 3 hours afterward and died in an attack of vomiting. The

necropsy showed that the other organs were normal, the tumor on closer examination proved to be the remains of a fetus and the case one of **fetus in fetu**. [W.S.N.]

6.—Monsarrat reports 4 cases of **laparotomy for intussusception**; 2 recovered and 2 died; one of them, with only mild symptoms, was an invagination of the appendix. In none of these cases did he try the injection method, as he regards it as a loss of valuable time. It is not wise to allow the child to reach its limit of endurance before operating, besides one is always in doubt if the bowel has been reduced or not, and if so its tendency to recur. [W.S.N.]

8.—Russell has devised a **new operation for cases of severe hypospadias**. He first passes a thread through the glans and draws the organ into position, dividing all adhesions that may bind it down; then a tenotomy knife, with its edge toward the dorsum, is thrust through the glans close to its under surface; he next makes an incision from the base of the penis on one side, up along the organ, around the top, over the dorsum, and down the other side, to a point opposite the starting place; the loop of skin over the dorsum is freed, and the flap exactly resembles a clergyman's stole; the free top of the flap is then slipped over the glans and a pair of forceps, which have been passed through the opening made by the tenotomy knife, pulls this flap through the glans and the redundant portion of it is cut off, and the lateral portions are stitched to form the new meatus. The sides of this flap are then inverted, and stitched with Lembert sutures. The adjustment of the preputial flap, from where the loop was taken, is the same procedure as in circumcision, but one must bring the four edges at the top carefully together. This is all done under strict aseptic conditions. After the above operation has healed, a second follows which consists of a suprapubic cystostomy and closure of the perineal urethra. There is one point of paramount importance in this operation and that is to define accurately the ridge where the urethral mucous membrane merges into the skin of the perineum, and with great precision to cut the flaps exactly; the edges must approximate when the thighs are brought together, and are best held by collodion and not stitches. The eighth or ninth year is the best stage to perform this operation. [W.S.N.]

11.—Love sets forth the principles of the mastoid operations of Schwartze and Ballance and the serious disadvantages of both procedures compared with what he terms the **single channel operation**, in which the bone is dealt with as in the ordinary radical mastoid operation. Special attention has to be given to the upper and lower margins of the groove, which results from the removal of the posterior wall of the external auditory canal, for it will form the posterior wall of the new and wider canal, and the slit cartilaginous meatus must be closely applied to this new surface. The bony edges, therefore, must be smoothed off, and a plain walled cavity produced. The posterior superior wall of the cartilaginous canal is then slit throughout its entire length. The mastoid skin-wound is then closely stitched, and a careful packing *via* the external auditory canal causes the slit posterior cartilaginous wall to apply itself to the posterior wall of the widened bony canal. A groove of granulation tissue fills up the gap in the slit cartilaginous canal, and the result is a much widened canal through which it is easy to conduct future treatment, which consists almost entirely of careful packing with special absorbent gauzes. Individual granulation masses in canal or middle ear may require special treatment, such as the application of chromic acid. The accommodation is so ample for manipulation of this kind that grafting of pieces of skin would be easy through this external auditory canal. The advantages claimed for this method are: That the patient may resume work in a fortnight, as all bandages are removed by that time; the capaciousness of the widened canal, which admits of every part of the healing surface being viewed through the speculum; complete healing within 3 months, 2 dressings per week being sufficient, as a rule.

13.—Moore reports the case of a girl, aged 8, who died from heart failure after **insect bites** on the nose and in the orbit. At necropsy the primary area of infection was found inside the lower lid of the right eye, from which infection had extended, causing orbital cellulitis. There were no signs of meningitis, but there were several pyemic infarcts in the left lung and a pyemic abscess beneath the visceral layer of the pleura. Bacteriologic examination of the blood

showed a general septicemic infection by **Staphylococcus pyogenes aureus**.

14.—Forrester made an autopsy on the body of a miner who was killed by an accidental **explosion of dynamite**. There was a wide laceration on the posterior surface of the left ventricle, extending to within a few lines of the apex, a second rupture on the superior surface of the left ventricle, and a third on the right ventricle. [J.M.S.]

1.—Tubby considers as a sprain injuries which may be so slight as to cause only temporary inconvenience or which may be so severe as to rupture ligaments or tear off a small portion of bone. Many different **methods of treating sprains** have been devised. The true treatment consists in the appreciation of the right time to apply different methods of treatment. Discredit is often due, not to the agent employed, but to the want of intelligence in applying it. At the time of receiving a sprain numerous small blood-vessels are ruptured and there is instantaneous pouring out of blood and lymph, which goes on for 3 or 4 hours after injury. During these hours the application of cold is effective. It acts as local constrictant of the vessels, lessening their size and limiting the effusion. If the amount of effusion is limited the probable stiffness is decreased and the time of healing is lessened. Pressure is usually applied by a bandage, but with the ordinary bandage the chief points of pressure are on the bony prominences about the joint. But the pressure should be made to bear evenly on all parts of the joint capsule. Hence it is important to wrap the joint with 3 or 4 layers of cotton-wool and place it in such a position that there is the least potential cavity for effusion and then firmly bandage the part. During the period of quiescence which follows the first few hours, slight effusion is still going on. At this time it is best to apply heat not only to diminish the pain, but the heat promotes absorption. After the hot-water bath the cotton-wool and bandage should be reapplied, also assisting absorption. During the period of absorption Tubby believes that the joint should be kept at rest. As a rule joints are rested too long. On an average, 3 or 4 days after the swelling has subsided the movement of the joint should be commenced. When the amount of swelling is considerable hot applications and rest are not sufficient, but properly applied massage is important together with gentle passive movements. Sometimes when the patient attempts to use the joint acute pain sets in, which is due to subacute or chronic congestion. In such cases absolute and complete rest is important. This is best obtained by applying plaster of paris, and from 4 to 6 weeks is frequently not too long a period. After removing the cast the joint is often stiff and painful, but the pain does not arise from adhesions but from conditions of the muscles which are

somewhat wasted and their tendons glued in their sheaths. In such cases Tubby prefers the use of friction, hot air and electricity to breaking up adhesions forcibly under an anesthetic. The practice of treating sprained joints by mobility from the first is believed to be applicable only in case of very slight injury, and if the symptoms become worse, permanent thickening and disability of the joint often remains. In the **treatment of fractures about the elbow-joint** except fracture of the olecranon, Tubby advocates the acute flexed position. If the arm is put up at a right angle, as is usual, a large mass of callus is thrown out on the front of the humerus, and at the end of 3 or 4 weeks the range of movement is limited to a few degrees. In the acute flexed position the ulnar and radial portions of the elbow-joint maintain the fractured parts of the bone in their proper position and the pressure of the coronoid process into its fossa maintains this comparatively free from callus. In treating separation of the lower epiphysis of the femur, division of the tendo-Achilles and forcible extension may be necessary if the line of fracture passes above the attachment of the gastrocnemius. In certain other cases the limb may be put up with the heel touching the buttock. In case both these methods fail Tubby advocates opening the joint and fixing the epiphysis in place with a steel nickel-plated screw. This is the best method to adopt in doubtful cases. [M.B.T.]

2.—Savage has undertaken a series of investigations upon 10 cases of **typhoid fever**, that are of extreme value. The objects, as he states them, were to determine whether the **serum reaction** is any aid to prognosis, and if any connection exists between it and the presence of complications or relapses; also to determine whether the blood of typhoid-fever patients agglutinates the *Bacillus coli communis* better than the blood of other patients, and whether the cases in which this reaction occurs have any peculiarity in their clinical course. Incidentally he determined the reaction of different varieties of typhoid bacilli to the blood of the same patient. Fourteen cultures of the colon bacillus were obtained, and a number of specimens of typhoid bacillus, 5 altogether. Two of these were not virulent, although they reacted. The blood was stored in sealed glass pipets, and the serum accurately diluted with a .75% solution of sodium chloride. The technic was exceedingly careful. In 3 cases, without complications, the reaction reached its maximum shortly after the temperature began to fall, and then also decreased. In one of these the most intense reaction occurred 4 weeks after the temperature had become normal. In 4 cases in which relapses occurred, the blood, shortly before the return of the fever, reacted very feebly, or not at all. However, this weakness of the reaction does not necessarily imply relapse, because it occurred in one other case. In other cases the marked diminution in the agglutinating power occurred after a hemorrhage, and is probably to be explained by it. Savage believes that the diminution in the intensity of the immunity attained is not the sole cause of relapses, but there is also, in all probability, an increased virulence of the microorganisms. The reactions made with the different specimens of colon bacilli gave some curious results. Of the 13 specimens, 11 failed to react, 1 gave a very slight reaction in 2 out of 5 trials, and another 17 positive reactions in a dilution of 1%, and 15 negative reactions. This micro-organism did not react with all cases of other disease, excepting one in which typhoid fever had probably been present, and another of appendicitis. Further investigations, however, showed that it was probably an organism that clumped readily. Testing the serum of the same case with different varieties of typhoid bacilli showed that a well-marked difference of the agglutinative power existed between the different varieties, particularly when bouillon cultures were employed. These facts, in Savage's opinion, are not sufficient, however, to justify the belief in distinct species. [J.S.]

3.—**Acute emphysematous gangrene** is reported following a lacerated wound of the right arm. A man of 26 was knocked down by a tramp and the skin was torn from just below the elbow to a point half way up the back of his arm. The wound was immediately cleansed and sutured under an anesthetic. Within 24 hours there was great pain and rise of temperature to 105.2. The arm was dressed and below the elbow an area of brownish-red color was seen. After the dressing the temperature fell but rose again and a crackling emphysematous "feel" was present in the tissues.

At this time the discoloration had extended and had become olive green in color. The arm was amputated at the surgical neck of the humerus, and the wound cleansed and sutured. On the third day there was recurrence of pain and the flaps were found to be gangrenous. Amputation at the shoulder-joint was performed. On the fourth day the temperature rose again and there was found gangrene in the flaps. A large area was excised and antiseptic dressings were applied. Several sloughs were removed at later periods and eventually a good recovery followed. A somewhat incomplete review of the literature of the subject of emphysematous gangrene is given. [M.B.T.]

4.—Gemmell reports 2 cases of **fibroid tumor complicating pregnancy** under his care during the last year. In the first, labor was complicated by puerperal eclampsia, and the delivery was with forceps, followed by such an acute peritonitis that on the ninth day an abdominal section was made. As the uterine wall contained many smaller fibroids, in addition to the removal of the large fibroid hysterectomy was performed, with ultimate recovery of the patient. In the second case, when the pregnancy had advanced 3 months, multiple fibroids, simulating retroversion of the uterus, were enucleated without interrupting the pregnancy. [W.K.]

5.—Buist mentions some work done by him 15 years ago in order to determine the cause of turbidity in tubes of **vaccine lymph**. He found that it was due to the growth of cocci, which are, he is now convinced, contaminations. He believes that the true organism occurs as a spore and probably cannot be cultivated. [J.S.]

6.—Griffith reports 2 cases of Landry's palsy. The first, a man of 40, had some pain in the limbs, followed rapidly by weakness and a right-sided facial paralysis. Then the muscles of the trunk were involved and at the end of 11 days the patient died of respiratory failure. The reflexes were lost from the beginning, but the sphincters functioned normally. The second patient, a woman of 24 years, noticed the earliest symptoms in the left hand, which became numb. Then there was dissociation of sensation in the left arm, and finally this spread over almost the entire left side, and then there was almost total anesthesia, except in the face. There was weakness, more pronounced on the left side, and finally bulbar symptoms. The patient died about 11 weeks after the onset. Griffith believes that Landry's palsy is a disease in which either the upper or lower neurons may be involved. [J.S.]

7.—Henchley attended 2 cases of acute articular rheumatism in the same family, both complicated by mitral regurgitation. The second, who may have contracted the disease from the first, developed pericarditis, thrombosis, and ultimately died. [J.S.]

8.—Durrant reports a case of **complete inversion of the uterus** following labor, with its reduction and recovery of the patient. [W.K.]

9.—Oxley reports 2 cases of **unusual conditions at birth**. In one case there was a fracture of the clavicle, which subsequently united satisfactorily; in the other, a congenital thickening of the sternomastoid, which gradually disappeared after delivery. [W.K.]

10.—The patient, 14 days before admittance to the hospital, had fallen in his yard and cut the side of his head. When admitted the wound was edematous; there was stiffness of the neck, inability to open the mouth, and **opisthotonos**. Mr. Barker injected **antitetanus serum** through the trephined opening, 7.5 ccm. being employed at this time, and 20 ccm. in the following 4 days, subcutaneously. In addition, massive doses of chloral were given. A week later the rigidity commenced to diminish, and in the course of three weeks the patient had completely recovered. [J.S.]

11.—A case showing that some women are liable to **abnormalities of gestation** on both sides of the body. The patient first had a 10 months' pregnancy without rupture, the child having apparently died at the end of 9 months. The operation showed a large, full-grown, dead child, which lay in a cyst which was an expanded portion of the left broad ligament. The placenta was attached to its posterior wall and was removed. The edges of the cyst were stitched to the peritoneum, the cavity was drained, and the patient made a good recovery. Some years afterward a second tubal pregnancy occurred on the other side with rupture of the tube, and repeated hemorrhages made a second operation neces-

sary. The pregnancy was in the fimbriated end of the right fallopian tube, or between it and the ovary, and was about the fifth month. The patient again made a good recovery. Such cases seem to point to some abnormality in the formation of the uterine appendages delaying the passage of the ovum, rather than to accidental causes. [W.K.]

12.—A man of 27 was suffering from shortness of breath and precordial pain, together with the physical signs of an aortic heart-lesion. He had never had rheumatism or chorea. On postmortem examination the mediastinum was found to be filled with a new growth which involved the glands at the root of the lung, surrounded the base of the heart and great vessels, and extended into the neck on each side of the trachea. No valvular lesion of the heart was found. [M.B.T.]

9. Cessation of Respiration During Chloroform Anesthesia, Due to Chewing-gum in the Larynx. E. PAYNE PALMER.

2.—Duel found a small piece of tooth, which had been broken off in the **antrum of Highmore**, 15 years previous to his operation. Several operations had been performed for the relief of the **empyema**, but were unsuccessful, as they did not allow free drainage; in the one he performed, the **antrum** was trephined over the lower portion of the canine fossa; his reasons for electing this method are, it is easy, it affords anatomically the best point for drainage, it permits an opening large enough to admit the finger for palpation; foreign bodies can be removed easily and it presents an opportunity for inspection if curettage is necessary. Food is less likely to be pushed into the incision which is easily healed. [W.S.N.]

3.—Geis uses $\frac{1}{2}$ grain of **heroin** as a somnifacient in the restlessness of phthisis. He administers the drug 1 hour before bedtime. He uses a combination of $\frac{1}{4}$ grain of heroin and chloral and bromid of sodium to prevent recurrent attacks of epilepsy, and to prevent hysteric manifestations. As an analgesic the author uses from $\frac{1}{4}$ to $\frac{1}{2}$ grain in combination with coal-tar products or salicylates for neuralgia, inflammatory rheumatism, and for the pain accompanying carcinoma. He reports a case of carcinoma of the rectum in which the patient took 16 grains of heroin each day for 14 days, without nausea, vomiting, or any toxic effect. [J.M.S.]

4.—Pettus reports a case of multiple aneurysms occurring in a fireman, a hard drinker and suffering from syphilis. Two were of the right subclavian, and another of the abdominal aorta, fusiform in shape, and extending from the celiac axis to the third lumbar vertebrae; the bodies of the last dorsal, first, second and third lumbar vertebrae were all eroded. Death was caused by the rupture of this one near the celiac axis. [W.S.N.]

5.—Cabot thinks the many poor results in the treatment of various long-standing sexual and urinary symptoms in the male are due to the careless way in which these cases are examined, and often a great deal of harm is done by the promiscuous use of instruments. The exact nature of the disease should first be understood, then the treatment begun. He mentions 3 cases to substantiate his statements. [W.S.N.]

6.—Herzfeld reports a case of femoral phlebitis which he believes was cured by unguentum Credé. [J.M.S.]

7.—Cooke in his study of the **rectum in both disease and health** finds that most of the instruments fall short of their object, and what is needed most is reflected light, with the patient in the knee-chest posture; this position brings the bowel almost in a straight line while the contents of the pelvis fall out, thus causing the rectum to become inflated with air. Some instruments inflate the rectum forcibly, this appears somewhat hazardous in certain diseases. The introduction of a **proctoscope** should be painless. For examining the first 2 inches the anoscope is employed and the most important observations here are in regard to the muscles. The proctoscope is next used and with a blunt hook probe the valves are studied, they are usually three in number. Instruments longer than 6 inches, the sigmoidoscope and the colonoscope, should be introduced with a great deal of care. Many extrarectal diseases may be diagnosed by this method, and it affords a direct method for making local applications to diseases within the bowel. [W.S.N.]

Medical Record.

December 1, 1900. [Vol. 58, No. 22.]

1. Pernicious Anemia and its Relation to Inheritance. CHARLES L. DANA.
2. Gastropstosis. GEORGE ROE LOCKWOOD.
3. On the Analogy between the Nervous Conductibility and the Electric Conductibility, and their Relation to the Functional Neuroses. A. D. ROCKWELL.
4. The Treatment of Typhoid Fever at the New York Hospital. FREDERICK L. KEAYS.
5. A Few Remarks Relative to Typhoid Feeding. WILLIAM M. BROWN.

1.—Dana describes the case of a man of 47, who presented the characteristic symptoms of **pernicious anemia**, and whose blood showed slow coagulation, numerous macrocytes, microcytes, and poikilocytes, as well as degeneration areas; the red cells were reduced to 1,400,000, and to 958,000 before death, and the hemoglobin was 25%. There was decided polychromatophilia. There were normoblasts and giantoblasts. The main point in the report is that the patient was the thirteenth of 14 children, all of whom were born dead with one exception beside this patient. The one other child born alive is dead from pneumonia. There was no history of syphilis obtainable in the family, and Dana believes that there was an evidence of a remarkable lack of vitality in the generation to which the patient belonged. He has not found any note of this lack of family vitality in monographs or discussions on pernicious anemia, but believes that it should be looked for, as it may lead to some new knowledge concerning the disease. He believes that pernicious anemia is the result of poor genesis of blood in that the cells produced have insufficient vitality and are readily destroyed. He considers that this explains the disease better than any theory which attributes the disease to a toxin or to any form of hemolysis acting upon properly developed blood. [D.L.E.]

2.—Lockwood concludes: (1) That in the great majority of cases an adequate cause for the **gastropstosis** is not discoverable; (2) gastropstosis does not of itself, in an uncomplicated form, produce symptoms; (3) the displacement of the stomach, however, is a predisposing cause of a variety of gastric neuroses, of sensation, motion, and secretion; (4) these neuroses are usually induced by some definite mental or physical strain; (5) the displacement of the stomach is a strong exciting cause for muscular atony, and atony is the most common cause for the symptoms presented; (6) a complicating atony is associated with a more or less profound neurasthenia, and that a direct relation exists between these two conditions; (7) gastric acidity is increased in direct proportion to the atony, unless counteracted by gastritis; (8) mild degrees of gastritis are apt to occur in stomachs that are displaced, but the symptoms are neither severe nor persistent; (9) gastritis occurring in atonic and displaced stomachs reduces the excessive acidity of these cases and seems to modify the severity of symptoms; (10) atonic dilation without mechanical hindrance is exceedingly rare; (11) dilation, or better, muscular insufficiency, may occur in gastropstosis from duodenal kinking, from arteriomesenteric constriction, or from pyloric spasm; (12) pyloric spasm is

common in displaced atonic stomachs with hyperacidity, and may lead to a temporary dilation; (13) in a large number of cases, inattention to the conditions of atony, of neuroses, and of gastric secretions has led to an unsuitable, insufficient diet which reacts both on general nutrition and on local conditions within the stomach; (14) surgical intervention is applicable only to the cases in which dilation exists. He does not agree with Meinert that 50% of girls at 12 years of age, increasing to 90% in young adult women, are subjects of gastroparesis nor does he find it a frequent complication of chlorosis, and believes it is rare in young people. Stiller's sign was not observed in those suffering from neurasthenia. In the treatment of these cases he found the "Preissnitz umschlag" and internal galvanism valuable in conjunction with physical and mental rest and proper medication. [W.S.N.]

3.—Rockwell's paper is a theoretic presentation of the suggestion that the "nerve current" may be considered to be **analogous to an electric current** when passing through a coherer of iron filings. Branly's theory is that each grain in the coherer is surrounded by a sheath of condensed ether, and that the grains are not in contact with each other. The electric discharge expands the sheaths of ether, and their mutual penetration changes the tubes of filings from a nonconductor to a conductor, while the shock contracts these sheaths and destroys their conductivity. In the same way he considers that the electric discharge may increase and develop the dendrites, and through a greater activity of the neurons tend to produce new protoplasmic growths. Reasoning upon this theory he believes that electricity must do good in many cases of hysteria in various forms, in neurasthenia, and in some mental derangements. [D.L.E.]

4.—The method of treating fever at the New York Hospital is, under one visiting chief, to bathe at a temperature of 102.6° in a bath at a temperature of 65°. Others start the bath at 80° and tub when the patient is at 103° or over, diminishing the temperature of the bath afterward to 70°. The 11 o'clock P.M. and 2 o'clock A.M. baths are omitted. A modification of the alcohol sponge which has been found useful is to have one person sprinkle the body of the patient with alcohol by means of a whisk-broom, while another person fans him to hasten evaporation. This method is found to be nearly as efficient as the baths, though less stimulating. It is customary to give small doses of phenacetin or acetanilid if the temperature does not react well to the baths, or if anything interferes with the use of the bath. In treating headache and delirium the chief drug used is sodium bromid. For sleeplessness the same drug, or trional, is usually employed. If ordinary measures fail in controlling nausea and vomiting, gastric lavage is done. In constipation the bowels are kept open in the early days of the disease by calomel and saline purgatives. Cathartics are not given after the first week. Distention is treated by turpentine, either by mouth, by rectum, or in stupes. Stimulation is given only when it seems definitely indicated. In pneumonia, unless there is some definite individual contraindication the tubs are continued. In nephritis the baths are stopped, antipyretics being used, if necessary, to control the temperature. Pulse tension is reduced by nitroglycerin and chloral hydrate, and diuretics are used or the patient is given hot saline enemata or hot irrigations with the Kemp tube. Milk is given in quantities of from 50 to 70 ounces. Other foods are not given unless milk cannot be taken or seems to disagree, but as soon as the temperature reaches normal the patient is given a chop or a boiled egg, and more food is added to the diet constantly as the patient is able to take it. [D.L.E.]

5.—Brown believes that **typhoid fever**, while primarily a specific toxemia, is usually largely due to a secondary toxemia developed after the specific. He would give food that increases the quantity and activity of the digestive secretion and which leaves but little residue as a bacterial culture-medium, i. e., proteids and carbohydrates. He believes that milk is often not well digested, and that when it is not prepared it is practically a solid food and will take as long to digest as a solid food. We should not feed too often in order to give the digestive organs time to recuperate between the feedings. He states that proteids and carbohydrates give a smaller number of heat units while promoting the most effective digestive fluids, and should therefore be given for this reason also. [D.L.E.]

Medical News.

December 1, 1900. [Vol. lxxvii, No. 22.]

1. When Shall we Operate in Appendicitis? FRANK E. BUNTS.
2. A Medical View of the Treatment of the Cecum and Appendix. A. L. BENEDICT.
3. Therapeutic Studies of Heroin Hydrochlorid. BENNO HYAMS.
4. A New Operation for Hemorrhoids. ELLSWORTH ELIOT, JR.
5. A Plea for the Earlier Recognition of Squint in Children by the Family Physician and the Earlier Application of the Methods of Treatment. C. A. VEASEY.
6. The Treatment of Pneumonia with Antipneumococcic Serum. EDWIN ROSENTHAL.

1.—Bunts believes the question, **When shall we operate in cases of appendicitis** and when not? has no definite answer and never will. He divides the cases into 5 classes: 1. Cases recognized as appendicitis at their inception, of moderate severity. In these cases he finds a blood-count of great value, and is more inclined to place reliance upon it than either the pulse or temperature. An increase in the leukocytes is indicative of increasing inflammation, while a stationary leukocytosis shows that inflammation is decreasing. 2. Cases recognized as appendicitis at their inception and characterized by great intensity of symptoms. These call for operation at the earliest possible moment. 3. Cases not recognized as appendicitis until several days have elapsed, symptoms then becoming pronounced. If the blood shows increased white cells, operate; if stationary, delay is under the circumstances permissible. 4. Cases recognized as appendicitis in which the surgeon is not called until symptoms have started to subside. These cases do not require operation and it is safe to postpone until another attack occurs. 5. Cases in which delay has resulted in general peritonitis, etc. These unfortunate cases depend upon the surgeon's willingness to take the risk of censure and give the patient a last chance. [W.S.N.]

2.—Benedict, discussing **appendicitis**, gives the following points in regard to operation. In the very beginning the mortality is practically that of the operation itself; until the third day it still remains low, but after the fourth day probably nothing should be done excepting the evacuation of pus. If all cases in which there is tenderness over McBurney's point are considered appendicitis, it is probable that the mortality from either medical or surgical treatment is the same. After medical treatment relapses are common, and they may even occur after the appendix has been removed. The only unpleasant after-effect of the operation is hernia. Benedict becomes slightly sarcastic regarding the radical operators, and argues that there is as much reason to operate upon every case that presents the initial symptoms of appendicitis, as there is to amputate the leg of every person who sprains his ankle. The important thing is, of course, to differentiate between the **catarrhal and nonpenetrating forms**, and the **septic and gangrenous forms of appendicitis**. He gives the following general rules: A temperature in the beginning of 102°, or a temperature above 100° continuing until the second day, indicates operation. A rapid, feeble pulse, without rise of temperature, suggests a gangrenous or septic process. Leukocytosis of more than 20,000 indicates operation. Among the local symptoms he mentions tenderness, muscular rigidity, etc., and among the general symptoms vomiting with much nausea, and the general appearance of the patient indicates serious disease. He calls attention to the value of an excess of indican in the urine as an indication of intestinal stagnation and putrefaction. He then suggests the following medical treatment for suitable cases. All food should be withheld; moderate purgation with small doses of calomel and salts should be used; then intestinal antiseptics should be administered, such as mercury, silver, resorcin, salicylics, etc., the latter being especially effective; and then, as the patient recovers, careful dieting. If the disease has become chronic, the important factor in the treatment is the diet, which should be nonirritating and consist largely of vegetables. The meals should be given at regular intervals, and gastric digestion should be carefully stimulated. Medical treatment consists of the administration of some protective, preferably bismuth mixed with an oil, such as pure petroleum. Treatment may be continued for several months. [J.S.]

3.—Hyams reports his results of the use of heroin in various conditions of severe cough, such as asthma, chronic bronchitis, acute miliary tuberculosis, acute bronchitis, pulmonary tuberculosis, and whooping-cough. In all these the effects were favorable. It was also used in a case of angina pectoris with good results, and in a case of diabetes mellitus without effect. [J.S.]

4.—Eliot has devised a new operation for hemorrhoids; his idea is to do away with the loss of mucous membrane that occurs after most of them, and avoid contraction of the cicatrix. Opposite the base of the hemorrhoid, parallel with the mucocutaneous junction, a curved incision is made, and is carried upward on the same plane as Whitehead's operation. A second curved incision is made, forming an eclipse at the poles, of which an incision is carried upwards, giving 2 rectangular flaps of mucous membrane; the hemorrhoidal mass is then ligated with catgut and removed, the flaps are then stitched with a small piece of the catgut ligature left protruding to act as a drain. [W.S.N.]

5.—Veasey calls attention to the indifferent way the profession deals with squint in children, and he believes where it exists, the earlier the cause is recognized the better for the patient in after-life. [W.S.N.]

6.—Rosenthal employs antipneumococcic serum in the treatment of pneumonia. In complicated cases he follows this by an injection of antistreptococcic serum. He also uses the ordinary methods of treatment. The results should be apparent in from 24 to 48 hours. [J.S.]

Boston Medical and Surgical Journal.

November 29, 1900. [Vol. cxliii, No. 22.]

1. Acute Hemorrhagic Pancreatitis, its Surgical Treatment, with Report of Six Cases. F. B. LUND.
2. Observations upon the Symptoms and Treatment of Hyperacidity of the Stomach. HENRY F. HEWES.
3. Subperiosteal Fractures. FREDERICK J. COTTON.
4. Irritable Breasts, or Chronic Lobular Mastitis. R. C. CABOT.
5. Cyst of the Vocal Cord. J. PAYSON CLARK.

1.—To be treated editorially.

2.—Hewes has studied 48 cases of uncomplicated hyperchlorhydria. The most constant symptom was distress, the next symptom in order of frequency was desire to belch gas, then heartburn and pyrosis. Vomiting was seen in 17 cases only. In the majority of cases the symptoms were relieved by the ingestion of an alkali. Headache and nervousness were frequently associated with the gastric symptoms. In from $\frac{1}{4}$ to $\frac{3}{4}$ of the cases we can make a diagnosis from the symptoms. In the remaining $\frac{1}{4}$ the symptoms must be assisted by chemic examination of the gastric juice. In certain cases an increased or abnormal susceptibility of the patient to the secreted acid is a causative element in the case and the condition might be termed gastric hyperesthesia. Again the excess of acid irritates and retards the digestive and motor functions of the stomach. Therefore the treatment must be directed towards the reduction of the acidity of the gastric contents and toward the increase of the resistance of the patient to the acid. For these objects alkalies and large amounts of proteid food are useful. Starches should be limited, and sugars or predigested starches should take their place in the diet. [J.M.S.]

3.—Cotton finds that, on closer examination, subperiosteal fractures have little in common with the type known as greenstick fractures with which they are usually classed. He reports 10 cases of this kind, and concludes that such fractures in children, showing no deformity, and with no appreciable mobility, are not uncommon. They might readily be overlooked, since they often need no reduction, having no deformity, and they repair with callus formation quickly. The lack of crepitus and mobility seems to be largely or entirely dependent on the strength of the thick, intact, periosteal layer. There is no deformity, because there are no torn surfaces, no clean-cut crack, nor cross fracture, and no bent or half-broken layer of bone. Cotton has carried out some experiments on the cadavers of children, breaking bones by forcible bending and by direct blows. He finds that blows are less likely than slower-acting strain to produce typical greenstick fractures, and it is obvious that the soft bones of the

newborn may be broken or cracked in a clean-cut approximately transverse fracture-lines by forces moderate enough to leave the periosteum intact. [M.B.T.]

4.—Cabot reports 2 cases of lobular mastitis in unmarried women between 20 and 25. The lump in one case was about the size of a large horse chestnut, in the other a little larger; the chief symptoms were those of general debility. Both have improved under general treatment. One patient was obviously lacking in occupation and when an occupation was secured the symptoms entirely disappeared and the lump nearly so. The writer asks for further information on the pathology of this class of tumors, their usual course, and proper treatment. [W.K.]

5.—Clark reports a case of cyst of the right vocal cord in a man 25 years old who had had hoarseness and difficulty in speaking, beginning 12 years previously. On examination an oval, smooth, grayish-white swelling one-third the length of the cord was seen. This was incised with a concealed laryngeal knife, and a milky-looking fluid escaped. Nine months after the operation the patient has no difficulty in speaking. [M.B.T.]

Centralblatt für Gynäkologie.

September 29, 1900. [No. 39.]

1. A Case of Spontaneous, Complete Rupture of the Uterus. Conservative Treatment. Recovery. K. J. F. BAUER.

1.—Bauer reports the case of a secundipara, aged 25, in labor for 24 hours, suffering from unusually severe pains. When he first saw her she was completely exhausted, pulse 160, faint and fluttering; temperature 38.9° C. The pelvis was contracted in all its dimensions, and the fetus was unusually large. The fetal head was perforated and the forceps were used for the delivery of the dead male child. The uterus was found to have sustained an extensive laceration and the placenta had fallen into the abdominal cavity. It was found by means of the cord and with some difficulty delivered from among the intestines. The uterus and vagina were packed with iodoform gauze, the abdomen firmly bandaged and normal salt-solution was injected into both mammae to the amount of 600 ccm. The patient had slight fever, but was discharged cured in 4 weeks. Bauer quotes several other cases in which extensive lacerations, both of the uterus and the bladder, were healed without operative measures. [W.K.]

Teaching Hygiene to Women.—A Society for the Propagation of the Teaching of Hygiene to Women has been founded in France according to a vote of the Second Congress of Women's Work and Institutions. It is under the patronage of the heads of the medical profession and many leading teachers, and aims to make the study of the hygiene of the family and the child a compulsory part of all programs of female instruction and to establish lectures on practical hygiene for women aged 18 and upward in all towns and rural districts by societies and leagues of education.

Original Articles.

A TROPICAL RATION.

By J. R. KEAN, M.D.,

Major and Surgeon U. S. Vols.

Chief Surgeon, Department of Havana and Pinar del Rio, Quemados, Cuba.

"Si la maison importe a l'hygiene des tropiques je n'hesite pas a affirmer que l'alimentation y est comme le fondement même de cette science." (Treille, *Hygiene Coloniale*.)

In this discussion it is purposed to treat the question the importance of which is not overstated above, not from the point of view of the scientist, who deals in tables of relative proportions of proximate principles, and food-values, but from the standpoint of the soldier who eats the ration, and the company officer who does the military housekeeping. It will be assumed that the present United States Army ration provides an abundant and, in the main, satisfactory diet for temperate climates.

Starting thus from familiar ground we will undertake to determine:

- I.—WHAT, IN GENERAL TERMS, IS THE PROPER DIETARY FOR THE TROPICS, AND WHAT ARE ITS ESSENTIAL DIFFERENCES FROM THAT OF TEMPERATE CLIMATES?
- II.—IN WHAT RESPECTS MUST THE PRESENT RATION BE MODIFIED TO MAKE IT PROVIDE FOR, OR PERMIT OF, A PROPER TROPICAL DIETARY AND SO CONSTITUTE AN IDEAL TROPICAL RATION?

In connection with so rudely practical a machine as an army nothing is ideal which is not absolutely feasible, and so our ideal ration must be made to conform to reasonable limitations, as to cost, possibility of adequate supply, and other administrative considerations.

Before beginning the consideration of the proper tropical dietary it is well to point out the distinction between the ration which is provided and the dietary which is eaten. Food purchased with the company fund, for example, is usually not a part of the ration, but it is a very important part of the dietary.

A few words on the subject of the *flexibility* of the ration and the limitations thereof are also necessary. The word *flexibility* as applied to the ration will be taken to mean the quality of providing for variety in the diet and to include not only the alternative issues provided by Army Regulations Par. 1253, but also the purchase of increased amounts of articles issued, and of articles not issued, by means of a company fund. The commutation of the ration at \$1.50 a day to an enlisted man traveling alone—from which he may purchase whatever he likes, furnishes an example of the extreme of flexibility. The travel-ration issued to a company traveling by rail approaches the other extreme of inflexibility.

In European services where the service conditions are approximately uniform, and where local markets are always at hand, the system of money commutations is much used for peace conditions. For our service, with its frontier stations, and its widely varying local conditions, and local prices, such a system has been in the past inapplicable, and the flexibility necessary to escape a repellant monotony of diet has been gained by the familiar expedient of a company fund created by the sale of parts of the ration which are not at

the time desired. This, in practice, is equivalent to an optional money commutation of the articles on which a saving is permitted, while the presence of the components of the ration, at hand, if they are desired, secures the soldier against the inconveniences of an ill-supplied or extortionate market.

The articles on which the saving has always been chiefly made are bacon or pork, coffee, and, through the post bakery, flour. From the regularity with which a well-administered company makes a saving on these articles it might be inferred that the ration is in these respects too lavish, but this will be seen not to be true when it is observed that practically no savings are made in these or other components in the field under the conditions of active service.

The American soldier, unlike the European, receives in times of peace and in garrison a ration which is adequate for war conditions also. He is likewise more fortunate in that his pay is not laid under contribution to assist in feeding him.

The special conditions of the naval service make it practicable to employ in the United States Navy a much more extensive use of the system of money commutation than is practicable in the army. The flexibility of the ration has been markedly increased and a valuable addition made to it during the past year in order to meet the new requirements of colonial service, by G. O. 78, A. G. O., 1899, which permits a savings to be made on fresh beef and adds 2 ounces of dried fruit to the ration. Unfortunately certain restrictions are placed on this savings, as the provision that its money value must be taken in ham, or other articles of sale, and its limitation in amount to one-seventh of its issue.

The proposed changes in the ration refer, it must be understood, almost entirely to the dietary of garrison life, which is the normal life of the soldier. The limitations of field service are so narrow and so strict that there is little latitude. Bacon, biscuit and coffee must in the field be the soldier's fare, and the variations of the diet must come chiefly by individual or company purchase, for which he should receive a liberal cash commutation for the parts of the garrison ration which he does not receive.

I.—TROPICAL DIET.

The three proximate principles are classified as:

Fat, the heat food.

Protein, the tissue food.

Carbohydrate, the work food.

Atwater gives the amount of each consumed by the average American, with average work, as: Proteid, 125 grams; fat, 125 grams; carbohydrates, 450 grams.

"Cold increases the oxidation of the nonproteid material in the body, the increase being in a general way proportional to the fall in temperature. Conversely, a rise of temperature causes a diminution of oxygen-consumption and CO₂ elimination. The proteid material in the body is not affected."—*American Textbook of Physiology*.

As of the nonproteid principles, fat has, compared with carbohydrates, a heat-forming value of 2.2 to 1, the reason for the well-known fact that less fats are needed in hot climates than cold ones is sufficiently clear. There are, in addition, hygienic reasons why the carbohydrates should, to a great extent, be substituted for the fats in accordance with the law of isodynamic equivalents.

The digestion is weakened in hot climates and the

liver is more inclined to torpidity. Fats are more difficult of digestion and absorption normally than carbohydrates, and when freely ingested in the tropics are extremely apt to split up in the stomach into butyric, caproic, lactic and other irritating acids, producing a condition of hyperacidity of the stomach-contents, which the diminished secretion of the torpid liver is unable to neutralize and render alkaline. As the intestinal digestion cannot proceed in the presence of an acid reaction, the condition commonly known as "biliousness" results, with putrefaction of the intes-

amount of proteid taken is derived to a greater extent from the vegetable kingdom, as from the leguminosae. Physiologists and physicians, as a rule, state that less proteid is needed. This is, on the other hand, combated by some who maintain that less meat is eaten by tropical peoples because they are, as a rule, poor populations who cannot afford it, but that they gladly eat meat, when they can get it, in preference to a less stimulating diet.

Some observers, who have seen in Cuba and Puerto Rico the anemic and dropsical victims of ankylostomo-

tinal contents and the product of skatol, indol, and various other poisonous alkaloidal fermentation products. A catarrhal inflammation of the bowel results, with diarrhea. This diarrhea is at first of advantage in eliminating the poisons, but under the irritation of unsuitable diet the inflammatory condition is likely to continue and increase, running into the exhausting and dangerous diarrhea or dysentery which is so familiar to the military surgeon in the tropics.

It is certain that the inhabitants of warm countries eat less meat than those of cold countries, and the

miasis, have jumped to the conclusion that a stimulating meat diet is especially needed in the tropics. It is evident, however, that our English cousins in Jamaica, and other tropical stations, do not suffer from lack of proteid diet, yet their meat rations, both at home and in the tropics, is only $\frac{2}{3}$ of ours, viz., 12 oz. If our meat issue were reduced to this, it is certain that our troops would not suffer in nutrition, but would gain in health.

Treille, after showing that the diet of tropical peoples in Africa, Asia, Malaysia, Central America, and Poly-

nesia, is chiefly vegetable, the meat eaten being mainly fish, says: "In conclusion, the peoples indigenous to tropical countries are, above all, but not exclusively, vegetarians. These habits do not proceed, it should be observed, from a backward civilization. For the great oriental lawgivers, who were true hygienists, took care from the most ancient times to forbid by religious laws the abuse of animal diet. This was because they had cogent reasons for doing so, and these were drawn from experience. They knew that too carnivorous a diet disposes in warm climates to certain diseases, and they had reason to fear that these would result in injury to the development of the race or nation. Hence we find the prohibitions of the Mosaic and Mohammedan law, and likewise of the Vedic, Brahmanic and other religions of India where the Aryan race established so enduring a foothold. Of course the day has passed for imposing hygienic laws on entire peoples in the name of divine revelation, but these instances are quoted to illustrate one of the agencies which have favored in historic times the emigrations which have taken place from temperate and even cold countries towards the tropics. But is it not clear that in adopting traditions lived up to and proved by the results which we have mentioned we have not simple theories but a truly tested rule? The difficulty is to get it adopted by Europeans who in their turn are now invading tropical climates. Civilized man in our day is certainly more refractory than was the barbarian, to all restrictions placed upon his pleasures and tastes. Especially in the matter of diet he is so much the slave of national customs that it costs him much to break away from them."

The diet of the average American at home contains 125 grams of proteid, whereas only 40 to 50 grams are necessary (with abundance of carbohydrates) to preserve the nitrogen-equilibrium and prevent tissue-waste. It seems that such a proteid excess (*luxus consumption*) is less desirable and less harmless in the tropics. That this is true is shown by the fact that in India and other European tropical colonies, as soon as the wealthier natives begin to adopt European modes of life, they at once lose their relative immunity to dysentery, liver-abscess, jaundice, and like intestinal disorders which are the scourges of the European immigrant. It is a matter of common experience that in hot weather a diminished desire for meat on the part of most people is observed, and especially the kinds of meat chiefly eaten by the American soldier—roast (baked) beef with rich gravy, and bacon. At the same time comes a longing for fresh vegetables and fruits.

The appetite is lessened by long-continued heat and is more capricious. It craves *variety*, especially in vegetables and fruits, and a restricted and monotonous diet becomes distasteful and repulsive. Under these circumstances strength once lost is regained slowly, if at all, and convalescents do not entirely recover without a change of scene, which means, among other things, a change of diet. The importance of variety in the ration, and especially in the vegetable component, is, in the tropics, I believe, a matter the great importance of which has been overlooked.

On one point, and only one, I believe, in the whole subject of tropical dietetics are all observers agreed, and that is as to the disastrous effects of alcoholic excess in the tropics, though as regards to what constitutes excess there is not quite so much unanimity. Now alcohol is the instinctive resort of the bored mind, and the dulled appetite, the refuge from monotony of occupation and

monotony of food. The responsibility for much of the drunkenness in the army must be divided between the commanding officer who does not vary his drills and exercises, and the captain who puts every day before his men the never-varying dinner of roast beef and potatoes.

The need of ice in the tropics, both to preserve the perishable constituents of the ration and to furnish the cold drink which has from habit become indispensable to the American palate, is an obvious necessity, and it is equally clear that it should be furnished by the Commissary Department as a part of the ration. The cost in the tropics varies widely, and is often excessive, and it is not just or wise to saddle it upon the company fund, which will in isolated localities, where ice is most expensive, be most heavily taxed to provide the necessary variety in diet.

It may be argued that so far as ice-water is concerned this is an acquired taste and one which can be unlearned, and which is, from a hygienic standpoint, not desirable. Practically I do not concur in this view. Americans all have the ice-water habit, and if the soldier is compelled to drink tepid water, his thirst is not satisfied except with enormous quantities which upset the stomach and produce excessive sweating and loss of strength. There is also value in the fact that where the company is tied down to one source of supply, the company ice-water barrel or cooler, the purity of the supply is more easily safeguarded by the captain than if there is no such supply and the soldier drinks wherever he finds water. In the absence of the ice-water barrel the relative coolness of the surface-well is irresistible.

To sum up, the requirements of a tropical dietary, as compared to one suited to a colder climate, are: (1) Less fats and more carbohydrates; (2) less stimulating proteid in the form of meat; (3) greater *variety* of diet, both of meats and of carbohydrates in the form of fresh vegetable and fruits; (4) a fairly liberal supply of ice. These we will for convenience refer to as requirements 1, 2, 3, and 4.

[To be concluded.]

THE X-RAYS IN THE TREATMENT OF CARCINOMA.

By WALLACE JOHNSON, M.D.,

of Washington, D. C.,

Demonstrator of Pathology, Georgetown University Medical School, and in Charge of the Pathological Department of the Lionel Laboratory at the Central Dispensary and Emergency Hospital,

AND

WALTER H. MERRILL, B.L.,

of Washington, D. C.,

In Charge of the X-Ray and Photographic Department of the Lionel Laboratory at the Central Dispensary and Emergency Hospital, Washington, D. C.

SINCE the announcement, in 1896, of Prof. Röntgen's discovery of a new form of energy to which he gave the name of the unknown or x-ray, rapid improvement has been made in the manner of ascertaining the practical utility of these rays, and medical science especially has profited by new and numerous applications. At first the surgeons took advantage of this force to verify their diagnosis and assist in the proper treatment of fractures and to locate suspected buried foreign bodies. Soon its use extended to diagnosis in internal medicine and later to the therapeutics of certain skin diseases, chiefly lupus, hypertrichosis, and the eczemas. This last use grew out of the discovery that

exposure to the x-rays under certain conditions produces a severe dermatitis. As yet medical literature has contained no reports of the effect of the x-ray as applied to cancerous growths. It is our purpose to draw attention to the possibilities in this line and to cite the results of a few cases in which such application has been made.

There is no disease that physicians like less to encounter than carcinoma in any of its forms, especially when it has progressed to the stage where the probabilities of its complete removal are slight. Few surgeons today doubt that carcinoma can be cured when it is localized and in a location favorable to operation. More often than not, however, cases are concealed until glandular involvement or widespread dissemination has occurred and the hope of a cure from operation is practically gone. This common and dangerous delay is due to the popular dread of the knife. If, then, we have at hand an agent that will effect the cure without the use of the knife or of painful caustics, one of the most frequent causes for neglect of the disease has been removed. We are firmly convinced that, by means of the proper application of this agent under conditions of no practical discomfort to the patient, we can bring about the painless removal of the slow-growing epitheliomas. These growths, especially when they occur on the face, are very disfiguring; if allowed to progress they produce a condition loathsome in the extreme. Treatment of such cases by the x-rays leaves a remaining defect that is incomparably better in cosmetic results than that which must accompany extirpation by knife or caustic. Furthermore, our experiments lead us to believe that even in inoperable cases of carcinoma attacking superficial parts, we may give great relief from pain and can even slightly prolong life. If we can dispense with the use of opiates in this class of cases and free the patients from pain while leaving the intellect clear and digestion undisturbed, we have made a great improvement in the therapeutics of this condition.

To substantiate our statements we offer the following reports of cases already treated. In a later paper we hope to show the results of several cases now under treatment:

CASE 1.—Mr. G. is a professional man, aged 45, with good constitution and a good health record. His father died of cancer of the lower jaw. Eight or ten years ago he noticed on his left cheek a small pimple. Notwithstanding his applications it would not heal. His friends became alarmed and insisted that he see a surgeon. In 1894 the diseased area was removed and the actual cautery applied. A year later the ulcer had returned, larger than before; a second operation was performed with apparent success, but in 3 years the disease had returned in full force and a second center had developed on the right side of the nose. The several surgeons who had had charge of the case pronounced it epithelioma. As far as we could learn no microscopic examination had been made.

Condition on First Application for Treatment.—"There is a discharging ulcer on the left cheek, circular in shape, with a diameter of about 1.5 cm. The margin is slightly raised, is red and indurated. The central portion is concave, though usually filled with a dried secretion. On the right side of the nose is a second center of about the same size and character. This is located one-half on the ala nasi and one-half over the right nasal bone. The nose is considerably depressed at this point and is somewhat deformed."

The above description is taken from observations made at the time the treatment with the x ray commenced, September 6, 1899. The applications (described later in this paper) continued until October 9. The exposures were made every other day until 15 were given, 10 to the nose and 5 to the

check. A marked reduction in the quantity of the discharge was the first result noted. This appeared in about 3 days. Then the scab of dried secretion which formed, over these surfaces would form more slowly and remain adherent longer each time.

The last exposure, made with an extremely active tube, set up a severe dermatitis, though the application lasted only 5 minutes. The surfaces became inflamed, the discharge profuse and watery; a typical x-ray burn was produced. Treatment was suspended for 6 weeks. At the end of that time a healthy cicatrix had formed over both areas. When last seen, 6 months after the last exposure, smooth white scars slightly depressed, invisible at a distance from the patient, had replaced the original ulcers.

CASE 2.—Mr. I., a musician, aged 48, whose present physical condition and previous history were both good, applied for treatment February 17, 1900. Five years earlier the tip of his nose was accidentally scratched and, while the place was still raw, it was bitten by a fly. The part immediately became very painful and began to swell. Thinking that he had been poisoned, he consulted a physician at once, with the result that vigorous treatment with chemical caustic continued from that time until the above date. His physicians diagnosed the disease as lupus vulgaris.

FIG. 1.—Taken of Case No. 2, February 17, 1900.

Our notes on the case were as follows: "An eroded ulcerating surface with a border slightly elevated and indurated occupies the tip of the nose, extending on the right side about 2 cm. from the margin of the nares. The lower part of this area presents a defect where the ala nasi has sloughed away to a distance of nearly 1 cm. Through this defect the same eroding process is seen on the septum where at one place there is a perforation about 3 mm. in diameter. On the left side of the nose is an area of ulceration about equal to that on the right and closely resembling it in appearance, except that the ala nasi is not defective and the mucous membrane seems normal save immediately around the perforation in the septum. Connecting the two sides, a diseased area of 8 mm. in width extends across the bridge of the nose. A small nodule 3 mm. or 4 mm. in diameter about 1.5 cm. away from the upper edge of the ulcerating area on the right side toward the inner canthus of the eye. This nodule has not broken down and does not discharge. The whole surface of the ulcerated area discharges a thin serum which is somewhat offensive.

A small piece of the edge of the ulcer of the right side was removed for a microscopic examination; the result proved the disease to be an epithelial cancer and not lupus. (See microphotograph No. 3)

We began treatment at once, exposing the right side of the nose on every alternate day until it had had 3 exposures of an average length of 6 minutes each. One week later the left side was given 2 treatments. An interruption of 3 weeks followed, during which time a mild inflammation set up in and about the cancerous tissue. On March 31 the

FIG. 2.—Taken of Case No. 2, March 21, 1900.

second photograph here reproduced was taken. As the left side had not completely healed over it was given 3 more exposures. On April 14, the entire external surface was covered with healthy skin. A small diseased center still remained, however, about the perforation in the septum. Treatment at this place commenced May 12. The area is

FIG. 3.—From a section of specimen of Case 2.—Leltz obj. No. 3; oc. No. 4.

now progressing rapidly toward healthy tissue, though sufficient time has not yet elapsed to effect a complete cure.

The accompanying photographs, taken February 17 and March 31, indicate better than any description the original condition and the improvement.

[To be concluded.]

PRINCIPLES OF ASEPSIS APPLIED TO OPERATIVE AND OTHER WOUNDS OF THE EYE.¹

By EDWARD JACKSON, A.M., M.D.,
of Denver, Col.

OPERATING gowns, antiseptic solutions, specially prepared dressings, sterilizers, and routine methods of cleansing hands and instruments, are such evident and impressive methods of striving for surgical cleanliness that inevitably they have been given undue prominence in the surgical thought and literature of the years that have followed the discovery of the bacterial causes of suppuration. I would not underrate their importance, but at best they can only reduce to a minimum the virulence and the number of pathogenic organisms to which the injured part is exposed. No antiseptic routine can take the place of the natural barriers to infection that exist within the living body. Any routine that makes us forget and impair those natural barriers is to be condemned.

"The fact remains that under conditions much more favorable than we can hope to obtain by routine practice, the sterilization of even limited areas of the conjunctiva is practically impossible." I quote these words, not of some skeptic ignorant of bacteriology, dogmatically setting forth his guesses and impressions, but from a skilled bacteriologist, Harold Gifford (*Archives of Ophthalmology*, November, 1898), setting forth the net result of a careful experimental study of methods intended to sterilize the conjunctiva. And in his conclusions he is entirely in accord with other investigators in this field.

But because the conjunctiva, the lachrymal passages, and the skin of the lids cannot be rendered germ-free, it does not follow that all the efforts at cleansing them are useless. Every intelligent effort in this direction lessens the number of germs present, lowers their vitality, or washes away the toxins with which they would attack the tissues. Nothing is better established in bacteriology than the fact that when the number and virulence of the organisms is reduced below a certain level they will be unable to overcome the resistance of the tissues and establish an infection. But in any case a certain number of the bacteria will remain alive and capable of development under favorable conditions. Nothing but a sufficient power of resistance on the part of the tissues can prevent the manifestation of their pathogenic influence.

To avoid impairing the resisting power of the tissues is an indication of primary importance. An understanding of it has led to the discarding of the more active germicidal solutions for cleansing the eye. Reliance is to be placed rather on the thorough use of plain sterilized water, physiological salt-solution, boric-acid solutions, etc. In any of these the water is the important element. Judiciously used it accomplishes the mechanical removal of germs, with less disturbance of the tissues than is possible by any other means.

An apparent exception as to the stronger antiseptics is made of those cases in which there are marked evidences of existing infection, of eyes that are to be prepared for some important operation, like cataract extraction. In these cases repeated applications of strong solutions of silver nitrate, argentamin, or protargol are practised at intervals of one or two days. These applications destroy some of the bacteria, and lessen the

¹ Presented at the meeting of the Rocky Mountain Interstate Medical Association, Butte, Montana, August 28, 1900.

virulence of others. But they also provoke the more rapid proliferation of epithelial cells, and so increase the resistance offered by the conjunctiva. To be exact, this use of antiseptics is really the treatment of disease, that would threaten the result of an operation done while it was present. In the immediate preparation of the eye for operation strong chemical antiseptics have no proper place.

The need of avoiding any impairment of the resisting power of the tissues forbids another practice sometimes recommended. It is sometimes advised to test the freedom of the eye from infection by bandaging it for 24 or 48 hours prior to the time for operation. The bandaging of the eye so favors bacterial development that if pathogenic germs be present, it is argued that this bandage will cause the eye to become injected, discharging, and painful, from their increased activity, thus proving the unfitness of the eye for operation. This may all be true; and if, because of symptoms so developed, the operation is postponed and the preparatory treatment properly prolonged, the patient may be the better for it. But if no such decided symptoms are developed, the influence of the bandaging has still been in the direction of increased bacterial growth and activity; and the eye comes to operation in a distinctly less favorable condition than it was before the bandage was placed on it. In the long run, some eyes would be lost because of this impairment of resisting power. If, then, such a test is applied to it, the eye will be given its best chance for a successful result only by deferring operation. We must allow even the eyes which seem to bear the test, to recover their best condition, before proceeding to operate, just as we would have waited had they been rendered manifestly worse by such preliminary testing.

Of the natural guards against infection, one of the most important is bleeding, including the outflow of serum, from cut or injured surfaces. The minute currents flowing outward from every point of the exposed tissue sweep away invading bacteria, as no current or fluid from an extraneous source can. From the bottom of every pocket and cavity comes this flood of antiseptic fluid, washing outward the lodged and invading organisms. Those not swept away are entangled and sealed up in an antiseptic matrix, from which they can only be set free by its decomposition. The blood-clot forms a barrier to infection, second only to the normal epithelial coating.

[To be concluded.]

SUPRARENAL GLAND IN HAY-FEVER.*

By LEWIS S. SOMERS, M.D.,
of Philadelphia, Pa.

FOLLOWING the announcement by Bates¹ that the aqueous extract of the suprarenal gland possessed remarkable power as a local hemostatic and astringent in ophthalmic practice, numerous investigators studied the action of the drug both clinically and experimentally, and found that it possessed marked constricting action upon mucous surfaces and especially upon that of the upper respiratory tract. When applied locally to the normal or inflamed mucous membrane of the nasal interior, the parts become ischemic and contracted and the engorged vessels are relieved by the action of the drug.

When used intravenously, the physiologic action is expressed by an elevation of blood-pressure; the present trend of opinion being that this is a direct action upon the peripheral vessels, corresponding therefore to the results obtained from its local application to mucous surfaces. But two facts of major import must be noted when the gland is used in this manner; the first being that the rise of blood-pressure is rapid and evanescent and as promptly falls again; while in the second place, dangerous cardiac symptoms are also produced, practically prohibiting its use by this method, except for experimental purposes in the lower animals.

From a study of the physiologic action of the adrenal and from the favorable results obtained in a few cases of Addison's disease, it was but a step to the apparent indications for its administration both locally and internally, in the neurovascular complex of hay-fever. S. Solis Cohen² found that the symptoms of hay-fever from which he suffered were controlled by using a 5-grain tablet of suprarenal substance by the mouth, every 2, 3, or 4 hours, according to the results obtained. He also found that the associated coryza or sneezing would cease within 15 minutes after taking the tablet, and that these favorable results were more apparent when the drug was allowed to dissolve on the tongue, than when it was immediately swallowed. Similar reports have been made by Douglas³ and Bates,⁴ the former considering suprarenal extract internally as almost a specific in hay-fever, while Bates states that the disease has been completely relieved by taking the extract at intervals of 2 to 4 hours.

My experience with the internal administration of suprarenal extract in hay-fever comprises the study of 21 patients; 19 males and 2 females; the youngest being 17 and the oldest 56 years. The time during which the patients received the adrenal exclusively varied from 1 to 6 weeks, 10 being obliged to discontinue the tablets after a week's trial on account of disagreeable symptoms, while 7 used them continuously for 6 weeks and in 4 it was administered at irregular intervals, but at least 1 tablet daily from 2 to 3 weeks. The drug may be used either in the form of 5-grain tablets or in a glycerin-solution, the former being the most preferable as it does not produce the same degree of nausea as does the solution. I used the latter at first, but for the reason just given and the unreliability as regards accurate dosage, it soon became apparent that the tablets were superior, so they were thereafter used exclusively. The dosage practically followed that previously mentioned, all patients beginning on one 5-grain tablet every 2 hours and in those in which this produced unpleasant symptoms, it was given in the same amount every 4 hours, from 15 to 75 grains being taken daily, the latter amount being given to 2 patients, without, however, the production of any untoward symptoms or any appreciable benefit to the hay-fever.

Without going into details as regards the history of all the cases, 3 may be taken as types, especially as regards the violence and duration of the affection.

J. S., retired business man, aged 56 years, had suffered from hay-fever for 20 years, the disease usually appearing the first week in June and continuing until the first frost in the fall. For the past 5 years, at night or at any time during the day on the approach of a thunderstorm, asthma has appeared, and during the past 3 years the nocturnal

² *Philadelphia Medical Journal*, August 13, 1898.

³ *New York Medical Journal*, September 2, 1899.

⁴ *New York Academy of Medicine, Section of Laryngology*, December 27, 1899.

paroxysms of asthma have become so severe that he is obliged to sit at an open window, grasping the back of a chair, in order to obtain air. There were no gross structural abnormalities of the upper respiratory tract, and the urine was normal. Various measures had been used both to abort the attack and diminish its intensity, but were without effect when I first saw him, 6 weeks after the onset of the affection. He was given 5 grains of the suprarenal gland every 2 hours for 6 weeks, except for a few days at the end of the second week when he refused to take the drug on account of a marked increase in the chest-constriction and an augmentation of the asthma. He was persuaded to use the tablets again, but finally ceased entirely on account of the asthmatic symptoms.

A similar case was that of a bookkeeper, aged 58 years, to whom the adrenal was given in the same way 3 weeks before the expected attack, which was delayed 2 weeks, but then made its appearance as usual. The disease was of 4 years' duration and the asthma from which he suffered had appeared for the first time the previous season. As a result of the use of adrenal, the hay-fever symptoms were in no way changed, the asthma developed earlier than usual, was more severe and its intensity greatly diminished when the suprarenal extract was withdrawn.

A third case occurred in a boy of 17. The condition had existed for 3 years with mild nocturnal asthmatic wheezing from the first attack of hay-fever. The drug was begun a few days before the expected attack, which appeared at the usual time and continued until he went to the seashore, when it entirely disappeared. The effect of the adrenal was to slightly diminish the pruritus of the palate and chin, but was indifferent as regarded the other symptoms, the results obtained not being sufficient to warrant the further use of the drug after 6 weeks' trial.

Without going into the history of the other cases the effects of the drug may be studied as regards its influence upon individual symptoms. The nasal symptoms, as sneezing, rhinorrhea, and obstruction to breathing, were but slightly influenced; the sneezing attacks were apparently more infrequent while the drug was being used, but the attack in itself was as severe as before. The nasal stenosis was somewhat favorably influenced; in about one-half of the cases in which the obstruction was marked, there was diminution in size of the engorged turbinates; the rhinorrhea was uninfluenced in any way. The pruritus of the chin and buccal membrane was diminished in intensity when the tablets were allowed to dissolve in the mouth, but when they were swallowed no changes were observed, the same being the case with the eye symptoms, which in no instance were favorably influenced.

A feature of considerable importance was the effect of the drug upon the asthmatic symptoms in the six patients suffering from this feature of the disease. These, all of whom had had the asthma from 3 to 7 years previous, but in whom it had never appeared but at the height of the hay-fever season, were unfavorably influenced. The fact that the paroxysms were more frequent and of greater intensity when the adrenal was being taken indicated that the gland bore some causal relation. In support of this it was withdrawn for varying periods of time with a corresponding relief, and when again administered, the unpleasant features would become evident. Another aspect of its effect was that in 5 cases in which asthma had at no time previously existed, it appeared while the drug was being used, in all, however, in a mild form, and also disappeared not to return, when the drug was withdrawn. Possibly the appearance of the dyspnea was a coincidence, but both the patients and myself were convinced that it was the direct result of the drug.

The gland was given in two ways, by dissolving a tablet on the tongue, and by immediately swallowing

it; the former being the most satisfactory, as the physiologic action in some cases was to a slight extent produced in this manner, while, when it was swallowed, little or no appreciable results were obtained. The drug is practically inert as regards its effects upon the hay-fever. This, although clinically opposed to its administration in other affections, is supported by experiments in the lower animals, and to a still less extent in man. The majority of experimenters claim that the active physiological effects of the gland are not seen when it is given by the mouth.⁶ Its effect upon the mucosa of the upper respiratory tract is practically nil when swallowed, but when it is allowed to dissolve in the mouth, a slight action is observed, its beneficial action upon the pruritus of the palate being the direct result of its local use and not of its internal administration.

The untoward or disagreeable effects produced were nausea, a sense of chest-constriction, and the development of asthma or the augmentation of the paroxysm when it already existed. The nausea was slight and of little moment, rapidly disappearing within a short time and was not produced by an excessive dosage, as it was as frequent in those taking 5 grains daily as in those taking from 30 to 50 grains daily. The sense of chest-constriction was observed only in those with preexisting asthma or in those who developed it while under observation. It preceded the frank asthmatic attack by from 4 to 7 days, and disappeared within a few hours after the drug was withdrawn.

The favorable results obtained as seen in these cases were not of sufficient magnitude to recommend its use for this purpose, as it must be apparent that when administered by the stomach its effects are practically nil, but some absorption does undoubtedly take place, as shown by the unfavorable symptoms. A portion of each lot of tablets administered was used in aqueous solution to determine its local effects, so that while this report does not agree with the results obtained by the observers previously mentioned, the inutilty of the drug was not the result of inert specimens, as its active local effects occurred promptly in all the cases. It was also administered in conjunction with other measures after being used alone, but no special beneficial effects ascribed to the adrenal could be observed.

From the small number of cases here recorded, no sweeping conclusions can be formulated, but, of necessity, an unfavorable conclusion can only be drawn and I would not therefore recommend a long trial of the internal use of the drug in hay-fever.

In conclusion a few words are necessary as to its local value in this disease; here it is of great service, and when applied to the mucosa of the nose and pharynx, we can depend upon restoring the nasal respiration, diminishing secretion and sneezing attacks, and practically making the patient comfortable so long as the applications are continued. Internally, therefore, I consider the suprarenal gland of little or no use in the treatment of hay-fever either with or without conjoined treatment; but locally, in conjunction with measures suited to the individual case, I believe it to be the most satisfactory single remedy that we at present possess.

SANITARY WORK IN THE CITY OF HAVANA.

By W. N. BISPHAM, M.D.,
of Havana, Cuba,
Assistant Surgeon, U. S. A.

It is my purpose in this article to show the profession at large what has been accomplished in the line of sanitation in Havana since the beginning of American occupation. There have been a great many reports in the newspapers about this work, but the articles have been written mostly by men who have no knowledge of the subject, and are not capable of judging it correctly. I was connected with that Department for a period of four months in the first six months of this year, and the data I can give are from my own observation. I will first give an account of the condition of affairs under the old regime.

I arrived in Havana in the middle of December, 1898, and the sanitation in the city at that time was truly deplorable. The streets were extremely filthy and ill smelling, and there was really no organized system of street-cleaning. The barrels and boxes of garbage and other refuse were allowed to remain on the sidewalks in front of their respective houses for days at a time, and the stench from them was horrible. There was a contractor who was supposed to remove the refuse of the city, but this was done in a half-hearted manner, and on an average, about seventy (70) cartloads a day were taken away. The filth thus removed was carted to an old city dump, which was very badly located in reference to general sanitation, or was taken to the country and spread over the land as fertilizer.

The houses are extremely poorly built for preserving the health of the inmates, though on account of their thick walls they are cool and pleasant during the hot summer season. The sleeping rooms are mostly on the first floor, and are not provided with windows so placed as to assure a draught of air through the room when required, thus not even allowing the alleviation of the universal dampness.

The closets are usually in the kitchen or next to it, and there being no adequate sewerage system they are connected with privy vaults which are mostly under the kitchen floor, allowing any gases to ascend and contaminate the food being prepared. The flush tank closets were only in the better class houses, and most of them were broken or extremely filthy. In by far the majority of houses the only convenience provided was an ordinary privy seat placed over an opening to the vault. None of these vaults were ventilated, and most of them were of the absorbing variety and were full of fecal matter. During the old regime these pits were cleaned by dipping the contents out in dippers and pouring it into large wine casks, which were removed on ox-carts when full and taken to the outlying truck farms to be used as fertilizer. In a number of instances the charges for the work were so high that the owner of the property closed his old vault without cleaning it and built another alongside. When there was connection with a sewer, odorless traps were seldom used, and the drains were allowed to become filled with refuse.

There were a number of sewers throughout the city, but they were small and square in shape, and when we first took charge of the city, most of them were clogged with refuse matter.

Bakeries and other establishments for the manufacture of foodstuffs were filthy, and the employes in

such places would often sleep on the tables used for the preparation of dough, etc.

Cow stables were to be found in every part of the city, and the cows were kept in them continuously. No attention was ever paid to sanitation in these places, and in a great number, the cattle stood upon the bare earth which was saturated with their discharges. As may be imagined, the odor was very offensive. No milk analysis was practised and the cattle were never carefully examined by the veterinarians.

The city markets were in a deplorable state. They were only cleaned once a day, and the refuse was allowed to be piled in corners or any place most convenient, as no receptacles were furnished for it.

The municipal hospitals were in such a condition of filthiness as to be beyond belief. They lacked medicines, instruments, and medical and surgical supplies of every description. As they were at that time, they rather encouraged death than assisted the recovery of the poor unfortunates sent there for treatment. There was practically no separation made of contagious diseases from other patients in the hospital, and in the military hospitals, yellow fever and smallpox cases were placed in the general wards.

There was no adequate isolation and disinfection of cases of contagious diseases in private houses, and though vaccination was compulsory, the law was never enforced.

All of these grave defects in the city's sanitation have received some attention, and it is my purpose in this article to show how far the work has been carried.

The streets all over the city have been repaired and placed in as good a condition as possible with the material used. No permanent street making could be accomplished until new sewers were laid, so the old streets could only be remacadamized, but this did away with the numerous holes and depressions in their surface which before were receptacles for dirty, stagnant water and refuse of all kinds.

The streets are now cleaned as frequently as in our best-governed cities, most of them being gone over once a day. Their condition under this treatment has improved immensely, and in my opinion they are kept in as good a condition as in any city in the States.

No garbage can at present be placed out in front of the houses until 10 o'clock at night, after which hour it is collected in special carts and taken to the city dump. This dump is not simply a place outside of the city where such material can be thrown, but where the refuse is placed in scows and taken out to sea a distance of two miles. Besides this, there is also a garbage crematory of 4 furnaces for the cremation of such filth as the refuse of slaughter-houses, etc. From 70 cartloads a day, the amount removed has increased to 540, and is still increasing. This method of removal is very thorough, and as good as that of New York or any other large American city.

There has been a decided crusade against the unsanitary plumbing which is found in most of the houses, and a great many changes have been made. Thorough house-to-house inspections have been made, and the condition of each one noted on a blank prepared for the purpose. These reports have been carefully gone over and changes recommended when necessary. Of course, the procedure is necessarily slow, but a great many changes have been made, and the work is constantly receiving the close attention of an army surgeon detailed for that purpose. Where there is sewer con-

nection, modern flush closets have been installed, and where only the vault system is practicable, the owner of the property has been compelled to keep it well cleaned, and in a large number of cases the hopper closet has been put in. In many cases the vaults have been ventilated and covered so that no gas can escape into the house.

The square drains have been replaced in numerous instances by round terra-cotta piping, and the tenant of the property is obliged to see that they are kept clean. Altogether the improvement is remarkable, and will be noticed by any careful observer. The sewerage system, though extremely important, could not receive much attention at first on account of the fight between the city and Dady, who was awarded the contract for new sewers by the Spaniards. The Engineer Department, though, has opened a number of them in the lower sections of the city and thoroughly cleaned them. Some time this fall it is proposed to begin work upon a new system which will be up to the standard in all respects. They will then be laid in every street, and will provide an outlet for the entire waste of the city. In this system no sewage will be allowed to run into the bay, but all of it will be conducted some distance out into the gulf.

This will cause a gradual cleaning of the harbor, which will prevent its being a constant menace to the health of the community.

The owners of bakeries have been obliged to keep their premises clean and in a sanitary condition, and if not found so by the inspectors, they are fined heavily. Once a week all the bakeries, groceries, butchershops and fruit stores are thoroughly inspected by the district inspectors and all foodstuffs found in a bad condition are sent to the garbage wharf, and there condemned and cremated. This work is watched very closely by the medical officers in charge, and there has been a noticeable decrease in the amount condemned, and on personal inspection I find that the goods on sale are of a much better class than formerly.

The cowstables now must be provided with cement floors, good drainage, and must be well ventilated. The animals themselves have to be removed from the city at night, and pastured in the outlying districts. Of course the most desirable thing would be the entire removal of such places from the city limits, but such a move must be gradual, though I hope it will come in time. In the meantime everything is being done to keep the dairies clean and the cows in good health. They are examined frequently by the city veterinarians, and all cases of any disease whatever among them are reported at once to the sanitary office.

The milk now is carefully analyzed at the city laboratory and a heavy fine is imposed upon those persons found selling an impure article. Before our arrival, milk was brought to town in tin bottles in panniers on ponies. A recently passed ordinance prohibits that, and most of the dairies are providing themselves with suitable wagons for its transportation.

The markets have been put in an excellent condition, though constant supervision is necessary to see that proper cleanliness is practised. They are now cleaned three times a day and at night the whole place is washed out. In addition to this, each stall has to be provided with a metal can for the reception of all refuse from that particular place. No one is allowed to accumulate rubbish near his stall, and every stall must be kept clean.

The butchers are not allowed to hang their meat in reach of the public, and after hours, that which has not been sold is placed in an icebox or covered up. In addition to these regulations, the foodstuffs on sale are carefully inspected by men employed for the purpose, and all spoilt or decayed articles are destroyed.

The municipal hospitals were placed under the charge of army surgeons, and a thorough renovation inaugurated. The buildings were cleaned, and the employes were compelled to keep them so. New supplies of all kinds, including bedding, furniture, instruments, etc., were purchased and the hospitals reorganized under the American system. Isolation wards for contagious diseases were opened and thorough reports of all cases were required. One of the most important reforms was the removal of incompetent men, and the filling of their places by men more abreast with the times. At the same time the private hospitals were put under surveillance and constant inspections made of them by medical officers of the army; as a result of this care the hospitals were, when turned over to the city authorities in April, well equipped, and their general condition would compare favorably with a great many excellent institutions of the kind in the States.

A thorough disinfecting department has been organized, and after every case of contagious or infectious disease, the premises occupied by the patient, and all clothing and furniture used is disinfected. According to a new law promulgated in the spring of 1899, all such cases must be reported at once to the Sanitary Department. Those doctors not reporting such cases are liable to a fine of \$50. The patients are at once ordered isolated, and on the recovery or death of the patient, the premises are disinfected as stated above.

This rule is particularly enforced in cases of yellow fever or smallpox. As soon as a case of yellow fever is reported, a man is sent to the house with instructions to place himself as a guard before the room occupied by the patient and allow no ingress or egress except with an order of the Department or the doctor in attendance. All linen, utensils, discharges, etc., are disinfected by him before they can leave the room. He has a tub handy, filled with a solution of mercuric chlorid 1:500, in which such things are immersed for 12 hours. These guards are changed frequently, and are also inspected often night and day to determine whether they are carrying out their orders or not.

On the recovery or the death of the patient, this man at once notifies the Department and a disinfecting squad is sent up at once to disinfect the premises. The walls, ceiling and floor of the room are washed out with a solution of mercuric chlorid 1:1000, and then the room is sealed and completely filled with formaldehyd gas under pressure, using the gas from one liter of the fluid 40% formaldehyd for 2,000 cubic feet of space. This I think without a doubt will kill all infection that may be present. After this has been done, the room is kept sealed for 48 hours and then opened by an agent of the Department. The same procedure is followed in cases of smallpox, with the exception that if possible the patient is sent to the smallpox hospital at once.

In the beginning of 1899, the law in regard to vaccination was rigidly enforced, and a number of physicians were employed to vaccinate all those that had not been before. In a few weeks work among the lower classes, 50,000 persons were vaccinated, and at present wherever a case develops all the people in the vicinity receive a protective vaccination whether they have

already been vaccinated or not. Now what has been the result of these different moves towards a more perfect sanitary condition? This of course is shown more readily in the mortality statistics, particularly as such records were well kept under the Spanish regime. In the following table the number of deaths monthly for 1894, 1899, and 1900 are shown, which is decided proof that the sanitary condition of the city must have improved wonderfully.

Year.	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Totals.
1894	505	483	548	506	576	595	736	736	583	545	597	697	7107
1899	1260	842	810	648	635	638	680	620	498	497	493	634	8153
1900	498	491	605	482	473	521	518	559	519				

After perusal of this article I sincerely hope that no one will retain the opinion that the sanitary condition of Havana has not been improved, as some correspondents may wish them to believe.

NASOPHARYNGEAL MYCOSIS, WITH REPORT OF A CASE.¹

By P. S. DONNELLAN, M.D.,
of Philadelphia.

Laryngologist to St. Agnes' Hospital.

THE patient under consideration presented himself at my clinic at St. Agnes' Hospital on February 1, 1900, with the following history: He is 42 years of age and always enjoyed good health except for the minor ailments of infancy and childhood. He never had any symptoms of throat trouble until three weeks previously, when he began to complain of difficulty in swallowing and constant desire to clear his throat of some obstruction. These symptoms were unaccompanied by any constitutional disturbance, his pulse and temperature being normal and his urine free from albumin. He denied specific infection and stated that his wife and 5 children were perfectly healthy. On examination of his mouth his teeth were found in unusually good condition as regards freedom from tartar and absence of decay except the two upper central incisors. A general hyperemia of his fauces and postpharyngeal wall was observed, while the faucial tonsils on both sides, part of the postpharyngeal wall and both surfaces of the uvula were covered with a grayish-white membrane, somewhat elevated from the mucosa, but closely adherent to it—leaving a bleeding surface when removed by the forceps.

Clinically the case resembled one of nasopharyngeal diphtheria rather than that of follicular tonsillitis, but the absence of albumin from the urine and of the Klebs-Löffler bacillus from cultures made from the membrane excluded the former disease. Microscopic examination of a portion of the membrane showed the presence of the mycelial rods or threads of *Bacillus leptothrix* arranged in parallel rows surrounded by masses of granular material. A diagnosis of nasopharyngeal mycosis was made and the patient was given a mouth-wash of potassium chlorate, one dram, and potassium bicarbonate one-half dram, to be added to a pint of warm water and used every three hours. He was also encouraged to smoke tobacco freely, drawing the smoke well back into his pharynx and allowing it to remain in contact with the membrane-covered area as long as possible. At each visit to the clinic, portions of the membrane were removed by Grunwald's punch-forceps and the underlying mucosa mopped with full strength hydrogen di-oxid. Under this plan of treatment the patient improved and the membrane gradually disappeared, except a small portion upon the surface of each faucial tonsil.

Nasopharyngeal mycosis, while a comparatively rare

disease, is of considerable interest to the practitioner because of the importance of recognizing its true nature and of avoiding a mistaken diagnosis. This is particularly true regarding diphtheria, with which it is most frequently confounded. In our city, the compulsory notification of contagious diseases to the Bureau of Health and the resulting hardship caused by placarding and quarantining the house in which the patient resides, render it imperative on the attending physician to make an accurate diagnosis in a suspected case, so as to avoid, if possible, serious financial loss and great inconvenience to the patient. Pharyngeal mycosis resembles diphtheria in the following particulars: A history of throat trouble of recent development; the presence in the pharynx of a membrane grayish-white in color, slightly elevated from the mucosa but closely adherent to it, and when removed by the forceps, leaving a bleeding surface beneath. Unlike diphtheria, however, there is no constitutional disturbance, albuminuria is not present and the Klebs-Löffler bacillus is not found in cultures taken from the throat. Microscopically, the membrane from a case of mycosis shows the parallel thread or hairs of *Bacillus leptothrix*—one of the Schizomycetes—imbedded in granular masses which contain the spores of the fungus.

This affection is absolutely noncontagious and usually pursues a prolonged course, though it may subside spontaneously and abruptly. It is very frequently associated with carious teeth and disordered digestion which seem to favor the growth of *Bacillus leptothrix*.

The treatment is first directed toward putting the teeth and digestion in good order. The use of alkaline mouth-washes has many advocates, though upon this point Jonathan Wright says: "If the morphology is carefully studied and properly understood, it would be impossible for any one in their proper senses to believe that topical applications will eradicate this mouth weed. It would be quite as sensible for a farmer to sprinkle his garden weeds with paris green instead of digging them up." The effect of tobacco has been beneficial in many instances. Newcomb² reported a case before the Section on Laryngology and Rhinology of the New York Academy of Medicine in which the patient, a young Swedish woman, obtained no relief from the usual remedies until she had smoked cigars for some days. Of radical measures, the application of the galvanocautery or the removal of small portions of the growth at repeated sittings, give the best results. This latter plan of treatment I have followed out in this case and I am quite encouraged with the progress the patient made toward recovery.

Malaria in West Africa.—According to the *Lancet*, Dr. H. E. Annett, of the Liverpool School of Tropical Medicine, returned to Liverpool recently after a tour of investigation in West Africa, extending over 8 months. Dr. Annett studied the conditions of tropical diseases over an area embracing 1,000 miles of the coast, extending his researches to Lokoja on the river Niger. He has accumulated a mass of observations on the relations between malaria and the situation, the geographical peculiarities, and the temperature. In the main these data bear out the theory already established by the inquiries of Major R. Ross, late I.M.S., and Dr. R. Fielding-Ould, that malaria is disseminated by the anopheles mosquito.

VOL. VI, No. 24

DECEMBER 15, 1900

\$3.00 PER ANNUM

The medical martyr is far from an unknown or rare figure in the history of the world. His most recent exemplification is to be found in the case of Mr. Alexander Stewart Brown, an English physician, who, while on a journey of recuperation from a traumatic injury, waded up to his neck to rescue a man who had fallen into the water, and at once proceeded with artificial respiration until the man was resuscitated. He continued on his journey, but was a few days later seized with pneumonia, from which he died. Certainly peace hath her victories no less renowned than those of war, and medical men have contributed their full quota.

The influence of alcohol in the causation of insanity is not as fully appreciated by physicians generally, and especially not by the laity, as by alienists, upon whose notice the unpleasant yet important truth has forced itself with the conclusiveness of demonstration. The evidence is both clinical and pathologic. It has been repeatedly shown that alcohol causes degenerative changes in the tissues of the nervous system. In a discussion of the duty of the State in the care of the insane Kraepelin (*American Journal of Insanity*, Vol. lvii, No. 2) states that of the patients in hospitals for the insane in the German Empire 10% have been committed on account of mental diseases due to alcohol. In some institutions the percentage is as high as 30, not including numerous cases in which alcohol has been an exciting but not the primary cause of the trouble—in cases of mania, epilepsy, and paresis. Experience has shown that about one-third of the living children of alcoholic parents are epileptic and that more than one-half of the idiots in the world are the offspring of alcoholic parents. Kraepelin goes so far as to consider intoxication a mental disturbance fraught with great danger to society. He points out also the frequency with which alcoholism is responsible for crime of various kind and degree. There is no escape from the fact that alcohol is a poison, especially to the nervous system, and whose effects naturally will vary with the amounts in and the frequency with which it is used and the stability of the structures upon which its influence is exerted. There is, thus, but one attitude for the conscientious physician to assume in this connection, namely, to look upon alcohol as he does upon other therapeutic agents, as, for instance, ether, chloroform, opium, as having a distinct and definite

field of usefulness, but not to be employed indiscriminately and habitually and in the absence of physiologic indications.

To Prevent Degradation and Crime.—Not to commend or criticise, but to arouse intelligent study of one of the greatest, if not actually the most important problem of civilization, we call attention to a noteworthy book by Dr. W. Duncan McKim, entitled: "Heredity and Human Progress." In view of the increase of certain criminal and defective classes, and of the necessity of preventing their existence rather than allowing their free multiplication, Dr. McKim advises "the gentle removal from this life of such idiotic, imbecile, and otherwise grossly defective persons as are now dependent for maintenance upon the State, and of such criminals as commit the most heinous crimes, etc."

Prescriptions in Newspapers.—From a Philadelphia newspaper we quote the following letter written by Dr. Guy Hinsdale concerning "Hoff's Phthisis Prescription :"—

Sir: The prescription published in the daily papers of November 28 would speedily poison any one who might be led to try it. It calls for $\frac{1}{10}$ of a gram of arsenic to $3\frac{1}{2}$ grams of the mixture, which is $1\frac{1}{2}$ grains of arsenic to less than 1 teaspoonful. This is thirty times as much arsenic as would be safe to give in one dose, and no one could take the amount with impunity. A few doses would certainly produce death. Permit me to say that medical prescriptions should not be published in the columns of newspapers. Mistakes are liable to happen, and harm result to the unfortunate who might try to use them without medical advice. Arsenic and cinnamic acid have never cured anybody of consumption, and the despatches from Europe to the Associated Press relating to medical matters are exceedingly unreliable and ought not to be given the prominence which they receive.

The danger from this practice may be better estimated when one thinks that the many papers of the *Associated Press* probably copied the prescription. In a paper in the *Bulletin of the American Academy of Medicine*, Dr. W. L. Pyle, among other absurdities of newspaper medicine, mentioned a special article entitled "Sleep cure for nervous diseases." This cure consists of the administration of "8 grams of bromin every 2 hours in a glass half full of water," and its discovery is attributed to a Dr. Macleod, of China. Of course some form of bromid medication is meant, but never once is this indicated; and the word bromin is repeated

over a dozen times in the article, this noxious drug being enthusiastically recommended in ignorance of its poisonous and caustic properties.

The Purposed Reorganization of the Medical Department of the Army.—In arranging for the military establishment necessary in the situation of the country, which requires neither explanation nor comment, the House of Representatives, following the lead of the Secretary of War, has provided, or more truly has not provided, for the Medical Department of the Army in a way that attracts attention and should receive correction. As is well known, for convenience of administration the medical officers in the permanent establishment are divided into graded groups commencing with lieutenants and ascending in rank with decreasing numbers until they culminate in one brigadier-general, the surgeon-general. These are the same subdivisions that obtain in other staff-corps and also in the line, except that the junior medical officers are first, not second, lieutenants as in the line and the engineers. Experience has clearly shown that such a system is the most convenient for administration, and that it affords a working basis upon which pay may be established. It is, as we have just said, the same in kind as obtains throughout the staff. It is not, however, the same in degree. The existing law, not the inchoate bill, provides under the surgeon-general 6 colonels, 10 lieutenant-colonels, 50 majors, and 125 officers who are captains after having served 5 years, and first-lieutenants previously. Of these 191 officers 1 in 30 is a colonel, and, therefore, the average number to be eliminated for each newly-admitted medical officer before he can reach a colonelcy is 30. He ascends through the whole column, but the 6 at the top may be regarded as making way for him practically simultaneously. In the Ordnance, which most closely resembles the medical in being a scientific corps with the first lieutenantcy as the junior grade, it is $16\frac{1}{2}$, and in the engineers, excluding their second-lieutenants, it is 17. The House bill provides, below the surgeon-general, 8 colonels, 12 lieutenant-colonels, or an increase of 2 in each of these higher grades, 60 majors or 10 more, and 240 captains and lieutenants, or 115 in addition. This is a total of 320 officers, or 1 colonel to every 40 juniors. That is an increase of one-third in the intervening numbers to be outlived before acquiring the topmost position open to promotion by seniority. While actually and properly increasing the aggregate number of medical officers, the proportion at the top is materially decreased, and experience has shown that, with that ratio, theoretically no one can attain the colonelcy before being overtaken with compulsory retirement at the age of 64. Practically, of course, there will be some colonels; there will always be 8 officers holding that grade out of the 320, but the probabilities will always be against any particular newly-appointed officer becoming one of the 8.

Now the medical officers say that is unjust. We think it is. They say that even after they become majors, and during the last 25 years it has required between 18 and 19 years' service to reach that place, they will have 9 files as it is called, 9 officers to outlive for every colonelcy gained; while, for example, the subsistence officers who supply food, the quartermasters who provide shelter and transportation, the pay officers who disburse, have only $4\frac{1}{2}$ seniors per man who block the way. Rank carries with it consideration and emoluments, and the medical officers insist, and we cordially agree with them, that they deserve fully as well of the country as those first described. This is so obvious on its face that it seems a plain duty for physicians of influence to point out to individual senators, and particularly to the committee on military affairs, this defect and to urge its relief. The medical officers themselves have no direct influence and no opportunity for concerted action. They are scattered not merely over the country but over half the world, with no local interests and in no case in connection with those in legislative power. They affect public politics no more than the leonids sway the solar system. It is more than charity, it is duty, to help those who cannot help themselves.

Besides the disadvantages to the medical corps, and therefore to the army, that flow from this condition, it reacts injuriously upon the profession at large. By implication it places those highly trained and very faithful men on a lower plane of desert than others whose duties relate, we may say, more to the dollar than to the man, and by so much it depresses medicine below trade, or commerce if one will. But beyond this sentimental view it cuts off from the youth of the profession prospects to which those who are capable and have the taste have the moral right to aspire. Our medical colleges may well complain not only if their ultimate goals are barred to their better alumni, but if the way is made so narrow and so arduous that they find it useless to enter upon the path. We appeal to the colleges actively to complain. The congress should see without argument and without persuasion the effect upon the army itself. It is poor economy not to obtain and adequately reward the talent best fitted for any particular object. However, that there may be no lack of light, we commend the subject to our readers and urge that at once they present the matter, temperately but firmly, individually to senators and collectively to their State delegations, insisting that mischief and injustice will be done if there is not an increase in the higher grades of the medical corps commensurate to that given other staff corps and proportionate to the number of the junior officers.

Scientific Work in Hospitals for the Insane.—Kraepelin, in a recent paper in the *American Journal of Insanity* (translated by Dr. Stewart Paton), gives voice

to the spirit of unrest which is now agitating some of the innermost circles of psychiatry. The demand is for more scientific work in the asylums, and for more opportunity outside of the asylums for trained observers to advance this specialty to an equal rank with the other branches of medicine. Kraepelin is very outspoken in his views, and for a German professor is not a little militant against the established order of things in the Fatherland. He claims that one of the greatest obstacles to scientific psychiatry in Germany lies in the fact that the chairs of mental diseases in the universities are held by asylum physicians, who, he says, show not the slightest evidence that they are equal to the scientific and pedagogic duties of their position. He despairs of having another Gudden, or Hagen, or Damerow, who, in their time could both manage an institution and do scientific work. There is no progress possible in the future, he thinks, unless the clinic is entirely separated from the asylum. Chairs in psychiatry must be held by men who have had experience in teaching, and who have done something to advance our psychiatric knowledge. To this end small psychiatric hospitals should be established in conjunction with the clinics, and these should be utilized for such cases alone as are valuable for clinical purposes. In this way the asylums could and should continue to take charge of the large mass of chronic cases which are not of such great value for teaching purposes.

The tone of Kraepelin's paper is rather pessimistic, and this will probably surprise some American readers who are accustomed to think of Germany as an ideal country for all medical affairs. It seems that many of the same defects exist there that are now raising such a strong protest in our own country.

Kraepelin's paper suggests to us one or two thoughts which may have practical bearing on this subject of asylum work in the United States. If boards of trustees could be educated to see the importance of spending more money on scientific equipments and less on merely enlarging their limits for new patients, a distinct step in advance would be made. The goal of a successful hospital or asylum should not be merely an increase of numbers. In some hospitals if the trustees could see the necessity of not providing for more than 100 to 125 patients, and of increasing the medical staff, paying better salaries, equipping laboratories, and subscribing to the world's neurologic literature, they would possibly come nearer to having a model hospital and one which could with advantage and reputation supplement the work of some active neighboring clinic.

The Modern Specialist and His Education.—The growing tendency of medical men to specialize has been commented upon favorably and unfavorably from many sides. This tendency seems to be growing more rapidly than ever at present, and the temptations to

physicians to take up specialties are certainly very great. It diminishes the responsibility of the individual, makes his work easier, more agreeable and lucrative. But it has an undoubted tendency, on the other hand, to narrowness, and the growing craze for specialists is fraught with grave danger to the public. In a recent inaugural address on surgery as a science and art, delivered at the opening of the winter session at Queen's College, Cork, Ireland, Yelverton Pearson (*Lancet*, November 3, 1900), professor of surgery at the college, gives some valuable suggestions as to the education of the surgeon, which have their bearing on the education of all specialists, and he calls attention to the dangers to which we have alluded. Pearson believes that the good surgeon should be acquainted with biology, natural philosophy, chemistry, anatomy, physiology, histology, pathology, and bacteriology. He lays special stress on the importance of anatomy learned by careful dissection and an adequate knowledge of pathology. In order that we may become scientific surgeons we must study closely the circumstances presented by the disease in both the living and the dead body. We must understand the nature of diseased processes, the means for the resistance to invasion of disease, the provisions for natural recovery, and the phenomena of natural and acquired immunity. It is in the possession of such knowledge that the truly scholarly and scientific surgeon or physician excels his more empirical brother, by watching and guiding natural processes of recovery, rather than in interfering with them by the indiscriminate use of drugs. He believes that besides this thorough scientific knowledge the art of surgery should be carefully studied. The ability to accomplish delicate manipulations is acquired by work in biologic and pathologic laboratories, by careful and continued use of knife and forceps in the dissecting room, and by practice in the application of bandages, dressings and splints in hospital wards. The greatest work that has been done in the history of surgery has been accomplished by men who have not specialized in the ordinary sense, but who have extended their work over wider fields. The names of Lord Lister, Jonathan Hutchinson, and Kocher, of Bern, are mentioned among others who have had such a training. The most successful specialists, such as Spencer Wells, and Lawson Tait, were men possessed of a broad and comprehensive knowledge of medical science as a whole.

This outline of the educational needs of the specialist in so broad a field as general surgery might well be applied to any of the specialties. At the present time we have among us too many so-called specialists whose only claim to special knowledge is a course of from three months to a year at the clinics of one or more of our large cities. Men who tire of the arduous duties of general practice and who have successfully treated one or two of the more common diseases which might

come under the treatment of a specialist, believe that they have discovered a special aptitude for such work, and after the most inadequate preparation set themselves up as practitioners of a specialty. The same broad general training which has been outlined by Pearson is absolutely essential to all who hope to accomplish the best work. In addition to this, practice in acquiring the art of the specialty is necessary. This cannot be accomplished in a short course of a few months' duration. It means years of expensive study, the drudgery of serving as an assistant to some master of the desired specialty for a goodly number of years, and settling in the vicinity of some large medical center and living without income while taking advantage of the material of established hospitals and clinics.

Acute hemorrhagic pancreatitis is a subject which has attracted considerable attention during the past 10 years. Fortunately the disease is a relatively rare one, and a report of experience in considerable series of cases is unusual. Lund (*Boston Medical and Surgical Journal*, November 29, 1900) reports his observations in 6 cases of this kind, an experience which has been equalled by few observers. In 5 of these cases operative treatment was undertaken, and in 1 case which was operated upon by Dr. John C. Monro, recovery resulted. As but 4 previous recoveries after operation have been recorded this case is of peculiar interest. A woman, 36 years of age, who had had three attacks of epigastric pain two years previously, was taken with severe pain in the epigastrium and left hypochondrium, accompanied by vomiting and moderate fever. On physical examination there was general abdominal tenderness, muscle-spasm, and an indefinite tumor was made out. A diagnosis of probable rupture of a gall-duct with retroperitoneal abscess was made, though the possibility of pancreatitis and of abscess of the pancreas or tumor of the kidney was considered. An incision was made in a median line. The omentum was adherent to the abdominal wall, and on freeing it the pancreas was found enlarged, hard, and nodular. A finger was pushed into the tumor in various directions with the hope of finding pus, causing moderate bleeding. An opening was then made in the left lumbar region for drainage, and the abdominal wound was closed. Through the lumbar opening a nodule was removed, together with some omentum and fat necrosis. The wound was packed with iodoform gauze and a glass drainage-tube inserted. Immediate improvement followed, but a second operation was necessary for drainage of pus pockets through the lumbar incision 5 weeks later. There was free discharge of pus which ceased in about 10 days. An uneventful recovery resulted. Since then, over a year ago, the patient has been in excellent health.

Of the 6 cases, 5 were women, and all were between 30 and 50 years of age. Four of the patients had gall-

stones. In no case was a definite diagnosis made, but a diagnosis was approximated 3 times. Besides the recovery mentioned, 1 other patient recovered from the operation, but died 2 months later because of inadequate drainage. There were 2 deaths from shock, and in one case operation was declined because of the poor condition of the patient.

Lund discusses the differential diagnosis of this condition from perforating gastric ulcer and acute appendicitis. The pain is not so sharp nor the tenderness so acute as in perforating gastric ulcer. There is moderate tenderness on deep pressure; in all the cases there was a sensation of fullness, as of a tumor in the epigastrium overlaid by the stomach. Muscle-spasm was not so marked as in perforating ulcer or acute appendicitis. An absolute diagnosis is generally impossible, but in most cases the symptoms point to an acute peritonitis originating in the epigastrium, which, from whatever cause, demands exploration of the abdomen. Milder cases of this affection may recover with or without operative intervention. Severe cases require operation, which should be performed early, because the primary hemorrhage leads to necrosis of the gland-tissue. The hemorrhage may be stopped and further necrosis prevented by gauze packing and adequate drainage. The patient is in better condition to withstand an operation earlier than later when weakened by suppuration. As the diagnosis is usually tentative, exploratory incision should be made in a median line above the umbilicus. In severe cases this may be done under local anesthesia. On account of the weakened condition of most patients, rapidity in operating is essential. The great omentum must be traversed, masses of blood-clot and necrotic fat should be rapidly evacuated, and further hemorrhage stopped by gauze packing. It is generally impracticable to search for bleeding points. When the mass of blood-clot or the diseased cavity has extended into the left lumbar region, adequate drainage must be provided by a lumbar incision made on the finger passed into the cavity. This dependent lumbar drainage Lund considers probably the most important step of the operation, since in most cases it will be impossible to drain successfully through a median incision. In case there are symptoms pointing to the left pleural cavity at the base, the subphrenic space should be drained by resecting the tenth or eleventh rib in a posterior axillary line in order to prevent perforation of the diaphragm by an abscess. So few cases of acute hemorrhagic pancreatitis with operation have been reported that every contribution to this subject has special interest. No doubt the possibility of finding this affection is too often overlooked by surgeons making a differential diagnosis in abdominal cases. Lund's suggestion as to lumbar drainage seems to be judicious and may lead to better results in the treatment of cases in the future.

Reviews.

Encyclopædia Medica. Under the general Editorship of CHALMERS WATSON, M.B., M.R.C.P.E. Vol. II—Bronchial Plexus to Digestion; Vol. III—Diphtheria to Food; Vol. IV—Foot to Hernia. New York: Longmans, Green & Co., 1900.

We wish to repeat and reemphasize what we said in regard to the general plan of this work in our review of Vol. I, published January 20, 1900. One of the greatest difficulties encountered by the editor of a large composite book is to see that all the details are included, and that overlapping does not occur. It is only after extended use of a many-volumed book that one can decide as to this; but we think, as regards this, that there is little to criticize and much to praise in the presentation of Mr. Watson and his collaborators. Another less difficult and more criticisable defect of which we feel compelled to speak is the neglect of cross-references. Concerning the deplorable omission of all therapeutic agents we spoke in a previous review. One cannot be sure that in an unfinished work the failure of cross references indicates a failure to treat the subject, and injustice to a work of such excellent and serious purpose as this would be inexcusable. Even if somewhere the following subjects are adequately set forth, it makes all the more noteworthy the failure to insert the cross-references. Surely the student and practitioner should be helped by mention of the following noticed in part of one volume: Bubo, Bubonic Plague, Cartilage, Carbuncle, Castration, Catamenia, Cathartics, Caustics, Chalazion, Chancre, Chancroid, Charbon, Chill, Chloasma, Chorion, Clonus, Collapse, Colostrum, Coma, Coma-Vigil, Confinement, Consumption, Convalescence, Counterirritation, Cramp, Cupping, Cyanosis, etc. The list could be indefinitely extended.

As to the articles themselves, they are almost always of a high order of merit. They are thoroughly "up to date," and yet conservative and trustworthy.

The mystery of the Englishman's spelling is, of course, illustrated. We do not find *aether*, as we had expected, and not even *gangrene*; and *choroid* is also given instead of *chorioid*; but, of course, *hemorrhage*, *anæsthesia*, etc., are clung to; we suppose from *etymological* reasons, and we see we shall have to wait until the volumes reach the letter O, before we can learn anything about the Esophagus.

Atlas and Epitome of Special Pathologic Histology. By Dozent Dr. HERMANN DÜRECK, Assistant in the Pathologic Institute; Prosector to the Municipal Hospital L. I. in Munich. Authorized Translation from the German. Edited by LUDVIG HEKTOEN, M.D., Professor of Pathology in Rush Medical College, Chicago. With 62 colored plates. Philadelphia: W. B. Saunders, 1900. Price, \$3.00.

This beautiful little book, the first of a series of three on special and general pathologic histology, treats of the "circulatory organs, respiratory organs, gastrointestinal tract." The plan of presentation consists in a short description of the normal histologic structure of each organ, followed by brief accounts of the respective tissue changes induced by the different morbid processes of diseased states, illustrated by admirable lithographic plates, each containing two or three figures, with explanatory text giving among other data the magnification and the specific stain or special technic used. The fidelity of these plates, in drawing and coloring, is well-nigh absolute. In the preface Dr. Dürk says that the drawings were made from his own preparations, and though their beauty must be evident even to the unfamiliar eye, yet the excellence of the originals and the accuracy of the pictorial reproductions can be fully appreciated only by those who use the microscope and are acquainted with modern histologic methods. The author warns the student that "it is impossible to master pathologic histology without direct microscopic study," and to perceive, as well as to see, these exquisite illustrations the visual image must be interpreted by the eye of the intellect.

The editorial additions are well chosen and instructive. The translation is agreeable and gives the impression of being faithful, none the less that occasionally verbs are in the wrong tense—page 8 or 19, for instance.

The letter-press is artistic. If punctuation is a matter of taste and not judgment, then irrelevant commas and aggressively superfluous semicolons are matters of curiosity and not criticism. However, every part of the work is obviously conscientious, and it has been a pleasure to review this book, in which there is so little to overlook and so much to praise without stint.

A Text-Book of the Practice of Medicine. By J. M. ANDERS, M.D., Ph.D., LL.D. Illustrated. Fourth edition, thoroughly revised. Philadelphia: W. B. Saunders & Co., 1900. Price, cloth, \$5.50; sheep, \$6.50.

One finds much to admire in this new addition of Anders' Practice of Medicine, especially its practical features.

The author evidently prefers conservatism to things which are only seemingly within the border lines of proof. In typhoid, for instance, he clings quite closely to the pathology of the disease as generally recognized, namely, the lesions found in the bowels, and dismisses the septicemic form with only a few words. This is doubtless the safest plan. Due credit is given most writers for their work in the different diseases, but it might possibly have been better to have mentioned the name of Vaughan and his coworkers in their great work in typhoid during the recent Spanish-American war, who, in their masterly paper (*American Medical Association*, June 5-8, 1900), proved that the specific germ may be carried by flies, and may be inhaled in the dust by troops on the march.

As in another recent work, the bacillus of Shiga is not mentioned as being one of the causative agents in the production of dysentery.

In malarial fever the name of Ronald Ross, who was first to prove that the mosquito acts as the intermediate host for the malarial parasite, has been probably unintentionally omitted.

The writer regards the Bacillus of Sanarelli as the specific organism of yellow fever.

In speaking of appendicitis, the author confesses that it is a surgical affection, and in its treatment the physician should at once also request the services of a surgeon, and failing in this, "the physician falls short of his duty."

The charts inserted on pages 150, 151, and 296, showing the morbid anatomy of lobar pneumonia and acute pneumonic phthisis, as well as the chart on page 296, are very commendable. There is no more reason why a student should not keep before the mind's eye the morbid anatomy of these diseases than that they should always remember the temperature chart.

All told, the work will be found a safe guide for the student and practitioner.

Modern Surgery—General and Operative. By JOHN CHALMERS DaCOSTA, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital and to St. Joseph's Hospital, Philadelphia. With 493 illustrations. Third edition, revised and enlarged. London and Philadelphia: W. B. Saunders & Co. Bound in cloth, \$5.00; in half-morocco, \$6.00.

We notice with pleasure the appearance of the third edition of Dr. DaCosta's Modern Surgery, because we feel that a useful book, written by an able man, finds a place of utility on even the crowded shelves of medical literature. It scarcely seems necessary to go over in detail that which has given former editions a wide sale and general acknowledgment of superior merit, and we will notice, therefore, more particularly those parts which make this edition an improvement on the former ones. The third edition in number of pages, shows an increase of 200. The general arrangement of the book is much the same, a few chapters being somewhat differently headed, and the titles at the top of the pages being much more specialized, so that the reader may more readily find the particular detail for which he is look-

ing. The greater part of the first half of the book deals with general surgery and differs little from the former editions, covering in an able way bacteriology, asepsis, the various forms of inflammation, and pathology, and the treatment of wounds, and general surgical infections. The latter part of the book is devoted to special surgery, and in this part we find the greatest change, especially in the insertion of new operations. The addition to this part of the volume seems to make the book absolutely up-to-date, especially in regard to operative surgery. Among some of the improvements which the advance in surgery has made necessary, may briefly be mentioned, Bier's method of amputating through the lower leg; the younger Senn's incision for removal of carcinoma of the breast; Harris' instrument for obtaining unmixed urine from each ureter; Bryant's method of colopexy; Halsted's method of suturing the bile-ducts; Laplace's intestinal anastomosis forceps; Braun's method of gastroenterostomy, and Fell O'Dwyer's apparatus for inflating the lungs in cases of pneumothorax. Two new complete articles have been inserted, one on the examination of the rectum, and another on the hot-air treatment of the joints.

When we remember the style with which the former editions were written, the apparent care taken in the elimination of useless theories and methods, the clear English which enabled easy comprehension of the substance under discussion, and the many other features, which have given this book a popularity sufficient to warrant the appearance of a third edition; we feel that we can conscientiously recommend this, the third edition of DaCosta's "Modern Surgery," first to the student who is initiating himself to the science and wonders of surgery, and secondly to the general practitioner who desires a cursory knowledge of those surgical diseases and conditions which an every-day experience makes it necessary for him to deal with.

Stringtown on the Pike. A Tale of Northernmost Kentucky. By JOHN URI LLOYD, author of *Etidorhpa*. Illustrated. Published by Dodd, Mead & Co. Price, \$1.50.

This has been called one of the literary successes of the year by critics who have become familiar with the story through its serial publication in *The Bookman*. For those who have reserved their reading until its completion, a greater enjoyment and truer appreciation of motives and methods is reserved. The volume has a vivid interest for the profession not only in that it is the production of a member of their own guild, but in the interesting medico-legal questions with which it deals. The matter of expert testimony is one of perennial interest, and the book presents an exceedingly able argument against the conclusiveness with which such testimony is usually regarded. One also wonders whether Professor Lloyd has only imagined the existence of a drug that would produce gradual death in the manner in which young Drew made his expiation, or whether he has accurate knowledge from which to draw his minute descriptions. There is much of the occult negro wisdom in prophecy fulfilled, given without effort at explanation, even the trite one of coincidence, and invested with an apparent realism that leads to at least a passing wonder as to the reasons for the coincidences which so increase the natural tendency of many minds toward mysticism. The book is scholarly and of sustained interest, mystic in many parts, but never fantastic, and well worthy attentive perusal. The volume is a credit to the art of bookmaking, and is artistically illustrated.

A Treatise on Appendicitis. By JOHN B. DEAYER, M.D., Surgeon-in-Chief to the German Hospital, Philadelphia. Second edition. Thoroughly revised and considerably enlarged. Illustrated with 22 full-page plates. 8vo. Philadelphia: P. Blakiston's Son & Co. Price, \$3.50, net.

The second edition of this well-known book has been considerably enlarged and carefully revised. A number of cuts have been added together with a new chapter on the pathology of appendicitis. The history, anatomy, etiology, pathology, symptomatology, diagnosis, prognosis, treatment, and complications and sequels are treated in a thorough manner

and at considerable length. The author's views with regard to the treatment of appendicitis are well known. He states that increasing observation and experience have confirmed him in the opinion that the most appropriate course to pursue in order that the best results may be obtained is to remove the diseased appendix as soon as the diagnosis of appendicitis has been made, provided the diagnosis has been made early and there are no complications that render immediate operation unjustifiable. The use of opium is strongly condemned, as it masks the symptoms, favors the retention of excrementitious material, decreases the activity of the elimination when it may be most important, causes distention of the bowels which may favor the spread of peritonitis, increases nausea and often induces a false hope of recovery without operation until it is too late. Operation is considered contraindicated in cases of diffuse peritonitis in which the abdomen is distended, the temperature high, the pulse rapid and of high tension and the patient's expression anxious and indicative of serious intraabdominal trouble, the bowels constipated and unable to cause the expulsion of flatus and in which vomiting is continuous and tenderness is diffused over the entire abdomen. Regurgitant vomiting is indicative of approaching dissolution and is a well-recognized contraindication to operation. The appendix should be removed at the primary operation in all but exceptional cases. The after-treatment of appendicitis is discussed at some length and very many valuable suggestions are given. An extensive bibliography is appended which will be of much value to those who are specially interested in this subject. This book has come to be generally recognized as the most satisfactory monograph on the subject of appendicitis which has thus far appeared. And there is much in the new edition which will help it to retain this enviable reputation. Original drawings of specimens in the author's extensive practice and many unusual and interesting cases are mentioned. The subject is one of great interest to both physicians and surgeons and all who are specially interested in it will desire to own the new edition of this valuable monograph.

Essentials of Histology. By LOUIS LEROY, B.S., M.D., of Nashville, Tenn. With 72 illustrations. Saunders Question-Compends No. 25. Philadelphia: W. B. Saunders & Co., 1900. Price, \$1.00.

This compend of histology will be found useful to one who has not the time to consult larger works on this subject. Leroy describes three types of muscles, namely: Voluntary, smooth, and heart-muscle. As the work will be largely employed by students it might seem questionable whether it is best to describe the "giant cell" with the other cells found in bone marrow. As to the technic of staining after imbedding in paraffin the author states that after the paraffin is dissolved off by xylol, turpentine, etc., it is then transferred to absolute alcohol and stained. It might be best to wash out the alcohol in water before staining in aqueous solutions, but this is doubtless what the author meant. The writer has adopted the latest method in spelling words. Most of the drawings are original, and there are few inaccuracies noted such as are frequently found, thus showing a careful review by both writer and publishers.

Diseases of Women. By HENRY J. GARRIGUES, A.M., M.D., Gynecologist to St. Mark's Hospital and to the German Dispensary, New York City, etc. Third edition, with 367 illustrations. Philadelphia: W. B. Saunders & Co. Cloth, \$4.50 net; sheep or half-morocco, \$5.50 net.

This popular textbook has been thoroughly revised and all material of lesser importance has been omitted. Numerous additions are noted which brings the work up to date. The illustrations are clear cut and ably serve their purpose in elucidating the text. The work, embodying as it does the great clinical experience of the distinguished author, commends itself, not alone to the student and practitioner, but to the specialist as well, because it epitomizes the best gynecologic literature of the day. In reading over the work one cannot but be impressed by the clearness displayed in describing the various operative procedures, and the therapeutic knowledge imparted. The systematic manner in which the chapters are arranged, renders the book valuable to those who turn to its pages for a hurried consultation.

Correspondence.

A NEW MEDICAL TERM—CEPHALOPLEGIA.

By H. C. WOOD, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE terms paraplegia, monoplegia, hemiplegia, are among the oldest in medicine. There is, however, a paralytic condition which is just as characteristic as is either of the paralyzes mentioned, and for which there is no good medical term in use. This condition is the congery of palsies which is often spoken of as bulbar palsy, pseudobulbar palsy, cerebral bulbar palsy, etc., which may be produced by disease of the medulla oblongata, or may have other cause. For this form of paralysis I would venture to suggest the name cephaloplegia; so that we would have the terms hemiplegia, paralysis of one side of the body; cephaloplegia, paralysis of the muscles about the head and face; paraplegia, paralysis of the lower half of the body; monoplegia, paralysis of one extremity or part. The present nomenclature is an absurdity, speaking of a "cerebral bulbar palsy" being the same as saying a "cerebral paralysis of the medulla oblongata."

NEW WORD-COINAGE.

By G. ALDER BLUMER, M.D.,
of Providence, R. I.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

Is YOUR correspondent not in error in alleging that we have in our language no equivalent for the word "Verschlimmerung?" "Worsen" is a strong English verb, both transitive and intransitive, and "worsening," though unusual, is an equally good participial analog of the rugged "Verschlimmerung." There was never any warrant *quoad* necessity for the word "ameliorate," so long as we already had "better" and "improve" with their corresponding nouns. Therefore let us not cumber our Anglo-Saxon speech with its congener "apejorate." Similarly with "belittle," to make small, and "lessen," to reduce in bulk, number, degree, state, or quality, why "parvify"? One would have less fear of the taking on of these new words, at the behest of your correspondent, but for the feeling that what the PHILADELPHIA MEDICAL JOURNAL sanctions, even tacitly, usually goes. An Edinburgh professor used to say that almost anything could be stated in terms of Anglo-Saxon if the effort was intelligently made, and to him, worthy soul, impenetrability of matter was not less but more obviously a fact in physics when he preferred to speak of it as the "unthoroughfaresomeness of stuff."

STERILIZING THE CLINICAL THERMOMETER.

By WILLIAM H. DYER, M.D.,
of Dover, N. H.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

TO THE busy practitioner, it takes too much time to mix antiseptic solutions in which to sterilize his thermometer, and generally washing it in water, wiping with a towel, and return to the oft-times already infected case, is the routine practice of, I may say, most physicians.

The antiseptic and germicidal power of formaldehyd gas is now well known. A few drops of a 40% solution of formaldehyd on the cotton in the bottom of the thermometer case, furnishes the most effective and easy method of sterilizing the thermometer that I know of. The gas is readily liberated from the solution of formaldehyd, and the thermometer case being nearly air-tight, the escape of the gas and evaporation of the liquid is almost nil. In this way the thermometer when in the case is constantly subjected to the germicidal action of the gas. Before placing it in a patient's mouth it is well to rinse it in water and wipe dry, as gas or solution of this strength is very irritating to the mucous membrane.

A HAT-PIN SIX INCHES LONG EXTRACTED FROM THE MALE URETHRA.

By THOMAS M. PAUL, M.D.,

of Hazleton Pa.

Assistant Surgeon State Hospital.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

E. A., aged 21 years. Family history negative. Had an attack of gonorrhea about 3 months ago, which is now cured. Came to dispensary October 21, 1900, and stated that about one half-hour before I saw him, he thought he would test himself for stricture. In order to do this, he introduced a long hat-pin with a round, black head into his urethra, and while drawing it backward and forward carelessly, it slipped out of his fingers. On examination, the pin could be readily felt in the urethra through the corpus spongiosum. The head was palpable in the perineum and the point a short distance behind the external meatus.

I endeavored to force the pin forward by fixing its head, pushing the penis back on its shaft and then grasping the pin near its point and drawing it forward with the portion of the penis that had been pushed back, at the same time releasing the pin's head. Despite the fact that this manipulation was conducted with very great gentleness, I only succeeded in forcing the point of the foreign body into the urethral walls. An attempt to grasp the pin's point with forceps introduced through the meatus signally failed. I noticed that at one point in particular the point of the pin had nearly penetrated the urethral floor, and thinking that it would increase the danger of infection but slightly if the skin was pierced, I decided upon, and carried out the following procedure: Fixing the head of the pin behind the scrotum with the fingers of one hand, and bending the penis upward on the abdomen and forcing it backward on the pin's point with the other hand, I caused the shaft to protrude. Seizing this I drew it outward until nothing but the pin's head was left in the urinary canal. The shaft of the pin was then laid back against the scrotum and the head forced forward through the external meatus. Grasping the pin's head in this situation it was easy to draw it through the puncture in the floor of the urethra.

The patient was advised to go home, go to bed, and was given lead water and laudanum to apply externally, and salol to take internally. He reported on the following day; there were no inflammatory symptoms, and the puncture was scarcely discernible. Since then I have seen the patient twice, and he is now perfectly well. The hat-pin was precisely six inches in length.

Agnew, in his textbook, accurately described the power of deglutition exhibited by the urethra when bodies are introduced from without, but states that foreign bodies are carried in the direction of the urinary current when they enter it from within. The above, as well as several other standard textbooks which I consulted, recorded no similar case, and no method was described by which a pin as large as the above could be extracted. For this reason the case appealed to me as being unusual.

A NEW PRINCIPLE IN HEART PHYSICS.

By D. T. SMITH, M.D.,

of Louisville, Ky.

Lecturer on Medical Jurisprudence, University of Louisville.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN the article on "Moot Points in Obstetrics" contributed by me to THE PHILADELPHIA MEDICAL JOURNAL, in the Prize Essay Contest of 1899, an effort was made to justify, on physical principles, the evolution of the contracting ring of Bandl in the uterine muscle. The principle has been still more extensively elaborated in the essay on the "Functions of the Fluid Wedge" in the writer's recently published "Philosophy of Memory, and other Essays."

The first application of the principle to the heart-musculature and function was made by Dr. Ewing Marshall, of Louisville, in a thoughtful paper read at the meeting of the Kentucky State Medical Association in 1892.

In the paper referred to, Dr. Marshall, while insisting that the ventricle elongates during systole, contended that this elongation is due to the contraction of the band of muscle that encircles the ventricles, especially the left, acting with predominant force on the fluid content of the heart-cavity on the principle of the "fluid wedge."

In this paper I propose to produce a reason for the fact that the heart-muscle is thin at the extremities, thicker at intermediate points, and thickest at the middle of the left ventricle.

The assumption by soap bubbles, toy balloons and the like, of the spheric form, has been claimed to be due to the fact that the sphere is the form in which the greatest possible content is embraced within a given extent of surface. This is the statement of an undisputed fact, but it is very far from affording an ultimate solution. It is true that in no direction can the form of a spheric capsule be changed without diminishing its content, provided the extent of surface remains the same.

The principle in the raindrop is the same, except that the fluid wedges of the soap-bubble are controlled by external pressure and those of the raindrop are drawn by the force of gravitation to the center.

Without going more extensively into an analysis of the intricate physical principles here involved, it may perhaps be enough to say that it requires less force to clamp about the middle of an elastic bottle, or the uterus, or the heart, and expel its contents than to accomplish this by pressing over the whole surface of such receptacle.

And just here it is pertinent to note a certain difference between the hydraulic and hydrostatic action of fluids.

In the so-called hydrostatic paradox we are taught that in stable fluids each particle presses equally in every direction.

This, though in my opinion not a paradox at all, but an instance of a general uniform law, is at least a fact. But it applies only to fluids in equilibrium and not to such as are in motion. In stable fluids, no matter what the shape or size of the containing vessel, the pressure on its walls is everywhere the same at the same level. But let a measure of expanding force be released at any point in the fluid contained in the vessel, and it will spread or radiate just as light does, with an intensity inversely as the square of the distance it extends, or, as commonly stated, inversely as the square of the radius. That is to say, if at any point within fluid contained in a vessel, a cartridge were exploded with just force enough to rupture the vessel-wall at a single point, the rupture would take place in the part of the wall nearest to

the point of explosion, provided, of course, the wall was everywhere of uniform resisting power.

The bearing of this principle on heart physics presents itself in two important aspects for consideration. One is the economy attained in diminishing the capacity of the cavity of the heart and thereby lessening its content by changing the form of the organ from that of the spheroid to that of the cylinder. The other is the evolution of the greater thickness of the muscle by which this object is effected, at those points where the greatest stress is imposed by this character of contraction; or, in other words, at the points where the walls approach nearest to the center of the heart-cavity in contraction.

The requirements which would seem to guide evolution would obviously be met by the production of such a structure of the heart as that the thick belt of muscle about the ventricles would be able in contracting exactly to counterbalance the action of the thinner muscles at the extremities, and there should be therefore neither shortening nor lengthening in a strictly normal heart during contraction. The empty heart in contracting will invariably shorten; while the muscular bands might in the case of full ventricles, as pointed out by Dr. Marshall in the paper already referred to, by means of the fluid-wedge action of the contained blood, drive out the thinned extremities and thus bring about more or less lengthening.

The uterus, in which great force is to be exerted for a similar purpose, namely, the emptying of its cavity, has a corresponding provision in the contraction ring of Bandl.

No similar feature has as yet been pointed out in the structure of the other hollow organs of the body, such as the urinary and gallbladders, the vesiculæ seminales, and the ampullary enlargements of the vas deferens. But I venture the prediction that a rudimentary development of a muscular band about these organs will be revealed on closer inspection, and especially in instances of hypertrophy.

In the urinary bladder, the conditions are such as to admit of the evolution of only the slightest trace of such a structure. In the first place, a notable development of such a structure would be dangerous to the integrity of the bladder-walls as they now exist, and would require a corresponding thickening. In the second place, had strong muscular walls been developed in the bladder along with its acrid, irritating contents, exposed as these are to a still more irritating fermentation, inflammation once set up would be continuous and in most cases eventually fatal. Even as it is, the spasmodic action of the musculature of the neck of the bladder is the predominant factor in perpetuating inflammation, as its prohibition is probably the greatest aid in effecting cure of such a condition.

Albuminuric Retinitis.—Rogers (*Transactions of the Rhode Island Medical Society*, vol. vi, Part i, 1899) attempts, by collection of statistics and by his own experience, to estimate the expectancy of life in those suffering from chronic Bright's disease, after the discovery of albuminuric retinitis. In his computation he excluded the cases of albuminuric retinitis due to the uremia of pregnancy, diabetes, scarlet fever, etc., considering only such cases as are due to chronic Bright's disease. He quotes the figures collected by Belt, showing a total of 419 cases, 72% of whom died within 1 year, and 90% within 2 years, only 9% living over 2 years. The author's 18 cases ran a very similar course, from all of which he concludes that about 7 patients out of every 10 who develop albuminuric retinitis during the course of either of the 3 forms of chronic nephritis will die within 1 year and 9 out of 10 within 2 years. [A. B. C.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended December 22, 1900:

Tuesday, December 18—College of Physicians, Section on Ophthalmology.

Wednesday, December 19—College of Physicians, Section on Otology.

Thursday, December 20—College of Physicians, Section on Gynecology.

Contagious Diseases.—Camden has adopted a resolution that policemen shall notify the Board of Health of any case of contagious disease found without an attendant physician.

Faith-Curists.—Sollenberger and Sheets, faith-curists who conducted the Beulah Orphanage or Fire Baptized Holiness Mission, Philadelphia, pleaded guilty to the charge of involuntary manslaughter, and were each sentenced to serve 3 months in the county prison. The charge preferred against them arose from the death of a 7-months-old child, an inmate of the institution, who was ill and for whom no medical attention was provided—reliance being placed on the faith-cure.

Charged with Illegal Practice.—The case against Dr. Louis H. Freedman preferred by a member of the Erie County Medical Society came up for hearing recently. A proposition was made in the name of the society to withdraw the case, provided the healer would pay the costs and leave Erie within 24 hours. He accepted the proposition. The case was for failure to comply with the State statutes relative to itinerant practitioners, whereby they are required to pay a license fee of \$10 per day.

Harrisburg Academy of Medicine.—At a recent meeting, Dr. C. L. KEENE read a notable paper upon **Diarrheal diseases of infants and their treatment.** Both in the paper and the discussion emphasis was placed upon the importance of clean and pure milk rather than upon artificial aids to digestion and aseptic food. A municipal farm to provide pure milk was suggested, and it was thought that boards of health could cooperate with physicians and parents looking towards this or some other method whereby pure milk might be always available for infant feeding.

An instructive lecture was given by PROF. J. M. T. FINNEY, of Johns Hopkins University, upon **The treatment of perforating gastric ulcer.** A resume of the literature upon the subject showed the comparative infrequency of the condition in the United States. The importance of an early diagnosis was dwelt upon. Wier, in 1891, was the first United States surgeon to operate. Out of 268 reported operations up to 1900, there were 139 recoveries and 129 deaths, a mortality of 41%. Of recent operations, the mortality was 38%. Of 35 gastric ulcers in the wards of Johns Hopkins Hospital there was perforation in but one case. The technic of recent operations for aortic and other large aneurysms was the subject of some additional remarks.

The Samuel D. Gross Prize of \$1,000.—No essay which the trustees deemed worthy of the prize having been received on January 1, 1900, they hereby announce that the prize will be awarded on October 1, 1901. The conditions annexed by the testator are that the prize "Shall be awarded every 5 years to the writer of the best original essay, not exceeding 150 printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens." It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery, and that on the title-page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery. The essays, which must be written by a single author in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of

the College of Physicians, 219 S. 13th Street, Philadelphia," on or before October 1, 1901. Each essay must be distinguished by a motto, and accompanied by a sealed envelop bearing the same motto, and containing the name and address of the writer. No envelop will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within 1 year. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

Vital statistics of Philadelphia for the week ended, December 8, 1900:

Total mortality	CASES.	376 DEATHS.
Inflammation of appendix 2, brain 9, bronchi 7, kidneys 13, lungs 50, pericardium 1, peritoneum 4, pleura 1, stomach and bowels 13		100
Lungs—tuberculosis of 57, congestion of 1, edema of 1, abscess of 21		80
Heart—diseases of 35, neuralgia of 3		38
Marasmus 8, inanition 15, debility 4		27
Diphtheria	135	21
Carcinoma of breast 1, face 1, liver 4, stomach 5, uterus 4, tumor of liver 1		16
Uremia 11, Bright's disease 5		16
Apoplexy 11, paralysis 5		16
Puerperal convulsions		10
Cerebrospinal meningitis		9
Old age		9
Typhoid fever	69	7
Brain—hemorrhage of 1, softening of 4		5
Croup 1, membranous 3		4
Alcoholism		3
Cirrhosis of liver		3
Obstruction of bowels		3
Dropsy		3
Whooping-cough		3
Scarlet fever	50	1
Abortion 2, anemia 1, burns and scalds 1, cyanosis 2, hip disease 1, dropsy 2, dysentery 1, epilepsy 1, remittent fever 1, hernia 2, influenza 2, surgical shock 1, septicemia 1, suicide—hanging 1, shooting 1, tabes mesenterica 1, teething 1, ulceration of stomach 1		

The Philadelphia Association of Medical Inspectors of Schools effected permanent organization recently by the adoption of a constitution and by-laws. The officers of the association are: President, Dr. J. H. McKee; secretary and treasurer, Dr. Frank C. Hammond. As at present constituted the executive committee consists of Dr. Charles A. E. Codman, chairman, and Drs. Charles A. Ayers, Truman Augé, George W. Bowen, William E. Robertson, and Howard B. Martin. Meetings of the association will be held at least once a month, at which papers will be read and topics discussed having relation to school hygiene, with the object of placing the work in this city on a solid foundation. So far the work of the inspectors has been entirely voluntary. They were appointed by the Board of Education last January. The corps consists of about 230 physicians, most of whom are well established practitioners, and very many of them are actively affiliated with the city's hospitals, dispensaries, and medical colleges. Women physicians are represented in the body by about 15 members. The Board of Education has requested Councils to appropriate \$25,000 for salaries of medical inspectors next year, and it is said that many Councilmen have expressed themselves as being in favor of the movement. The Chicago school authorities claim that fully 60% of the decrease of contagious diseases among school children in that city since the establishment of medical inspection there is undoubtedly due to the good work of the medical inspectors. The Bureau of Health statistics for this city show, it is said, that there has been a marked decrease in contagious diseases and of deaths from such causes among Philadelphia school children this year, and much of this health improvement is attributable to the voluntary services of the medical inspectors.

NEW YORK.

Memorial Hospital.—It is proposed to buy by popular subscription the Gaunt house in Burlington, N. J., and equip it as a hospital, commemorative of the faithful services of the late Dr. Franklin Gaunt.

The Syracuse Academy of Medicine proposes the appointment of 12 physicians for the county house hospital; 6 of them to be members of the Academy of Medicine, 3 from other towns within the county, and 3 homeopaths.

New York Hospital.—New buildings for this hospital were opened recently, consisting of a private patients' building, a dormitory building for employees, ambulance departments, governors' building, and out-patient department, all so arranged as to have abundant light.

The Buffalo Academy of Medicine, section of medicine, met December 11, 1900. The following papers were read: "Cyclic or Periodic Vomiting in Childhood," by Dr. Charles G. Stockton; and "The Treatment of Disease Locally by Hot Air," by Dr. Prescott LeBreton.

Adulterated Molasses.—As a result of an agitation now going on in New Orleans in favor of pure molasses the New York City Board of Health has taken action to learn if glucose syrup flavored with molasses is being sold in that city for the pure article, and samples have been gathered for analysis.

Typhoid in Sing Sing Prison.—There are now 17 cases in the prison hospital and additional cases are developing daily. It has been decided to fit up a wing in the new State building, as an emergency hospital. The water comes from the Croton reservoir and is boiled before it is consumed in the prison.

Suit Against Physicians.—Suit was recently brought against Dr. Rosenberg and Dr. Manges, of New York City, for \$60,000 damages. The jury failed to agree, the division being 9 to 3 in favor of the physicians. The suit arose from a simple curettage to stop severe hemorrhage in a woman with large uterine fibroids.

Tenement-House Problem.—The report of the tenement-house commission just issued deals with housing conditions in the 27 largest American cities and concludes that the tenement-house, as known in New York, is practically unknown in other cities of the country. In regard to provision for light and air, the members of the committee state that the laws of Buffalo, Philadelphia and Washington may well serve as models for New York.

German Hospital.—The first anniversary of this hospital in Brooklyn was celebrated on December 1, 1900, with appropriate ceremonies. The hospital now has room for 110 patients in the main building, and for 10 in the building for contagious diseases. A district covering a large territory has been asked for by the hospital for its ambulance service. The house staff now consists of Dr. George H. Reichers, Dr. Lester L. Reos, Dr. Albert J. Toerig, and John A. Ferguson.

Foreign Insane.—Goodwin Brown, connected prominently with the hospitals for the insane of New York State, in a recent appearance before the Industrial Commission urged that vigorous legislation should be made to protect the country from an influx of insane emigrants. He was not prepared to say that there was a concerted effort on the part of foreign countries to impose their insane upon the United States, but 50% of the patients in the hospitals for the insane in New York State are foreign-born, and the foreign insane are costing that State \$1,000,000 a year.

Rating of Physician Candidates.—The New York State Civil Service Commission has made an important change in the method of rating the standing of physicians who apply for positions in state institutions. It has decided to accept in lieu of the examination heretofore required the examinations for license to practice medicine in this State conducted under the authority of the University of the State of New York, and to enter accepted applicants for such positions upon the eligible list in accordance with the ratings obtained by them in the examination for license to practice. In conformity with this determination an eligible list will be prepared on December 15, containing the names of persons whose applications have been accepted prior to that date, and new lists will be made up from time to time in the same manner whenever required. The positions are open to men and women. The salary in most cases is \$600 a year and maintenance.

Widal Examinations at Quarantine.—Dr. Alvah H. Doty, health officer of the port of New York, announces that the Widal test for typhoid fever will be made free of charge in the laboratory of the quarantine station at the request of any physician in New York State. The material and full directions for securing and forwarding the blood or serum to the department for examination will be sent on application, and the result of the examination will be promptly communicated to the sender. These examinations are intended to put this important diagnostic aid within the reach of physicians in the country and in small towns where no bacteriologic laboratories exist.—[*Medical Record*.]

New York Academy of Medicine.—At a meeting of the Section on Orthopedic Surgery, held October 19, Dr. H. GIBNEY read a paper on the **Diagnosis of Pott's disease**, which was illustrated by the exhibition of photographs and the presentation of patients. He said a grunting noise with each expiration is almost always characteristic of caries of the dorsal region, and an early diagnosis is greatly assisted by the occurrence of gastralgia and the appearance of a careful gait and a peculiar apprehensive attitude, and an instinctive desire to avoid disturbance of the diseased vertebrae. The first sign of a kyphos is seen in a slight angle breaking the long natural curve of the spinous process observed in profile as the patient lies prone.

State Hospital for Tuberculosis.—The Board of Trustees appointed in May report that after 5 months' inspection of 26 sites in the Adirondack country, in which due consideration was given to water-supply, quality of soil, elevation, temperature, protection from wind by forest or hills, accessibility to railroad, etc., a suitable site has been selected in Franklin County at the west end of Lake Clare, which it is hoped may be purchased at from \$10,000 to \$12,000. By the terms of the act incorporating the institution such site is subject to the approval of the State Board of Health and the Forest Preserve Board from whom no decision has been rendered. The opinion is given that the hospital cannot be built and equipped at a cost less than \$200,000.

The New York Obstetrical Society held its regular meeting, November 13. Dr. E. B. CRAGIN presented a patient upon whom operation has been performed for full-term ectopic gestation, the child being alive, in perfect condition, and presented with the mother to the Society. As a result of 48 hours of spurious labor, the ectopic sac was found ruptured and the intestines covered with fresh fibrin stained with meconium. The point of rupture was quickly dilated with the finger and the living child extracted. The placenta was chiefly attached to the left broad ligament, and it was found that the maternal vessels supplying the area could be ligated. The uterus was so incorporated with the sac that it was decided to remove it, the sac and placenta en masse. Dr. Cragin, in closing, said that the best time to operate was 2 weeks before full term, so as to get ahead of the spurious labor, and in this way get a living child.

Dr. A. BROTHERS presented a specimen of **malignant chorion epithelioma**, or so-called **deciduoma malignum**, removed by vaginal hysterectomy performed under intraspinal anesthesia. Recovery was uninterrupted.

Dr. J. E. JANVRIEN presented a specimen of a **multilocular fibroma of the uterus** weighing 8 pounds, removed by abdominal hysterectomy. He also presented a specimen of **cancer of the uterus**, abdominal hysterectomy being complicated by ovarian tumor, an interesting case from the fact that this operation was preceded 5 years before by trachelorrhaphy and this was the first case in his experience where cancer of the cervix had developed after trachelorrhaphy had been done.

The paper of the evening on "**My failures and successes with spinal anesthesia**" was read by Dr. SIMON MARX. He said the causes of failure might be inert cocaine or the use of too small a quantity of it, but the largest number was due to nonentrance into the canal either from faulty technic or too short a needle. The author then described the correct technic.

New York Neurological Society.—At the regular meeting, November 6, 1900, Dr. M. G. SCHLAPP presented a case of **paralysis agitans without tremor**; the chief

features were rigidity of the muscles, the expressionless face, and the position of the arms, body, and hands. He also presented a case of **paralysis of the Duchenne-Erb type** in a man who had fallen from a bicycle, striking his shoulder; it was interesting because the anterior pectoral muscles were affected.

DR. J. FRAENKEL presented a case for diagnosis in a man, 40 years of age, a tailor by occupation, who claimed to have been well up to within 1½ years ago. About 18 months ago the man had been pushed roughly off a street car. On awakening the next morning at home he had been absolutely helpless, being unable to move his upper or lower extremities. After 6 months he had been admitted to the Lebanon Hospital, but had left there, according to the history, unimproved. On coming under the speaker's observation, there had been noted at once the presence of an extensive eczema. On a second examination the shoulder-joints had been found partially ankylosed, and the muscles surrounding them had appeared atrophic. There was also atrophy of the supraspinatus and infraspinatus, and slight atrophy of the serratus muscle. The electrical reactions were not changed. A thorough examination of his nervous system had proved absolutely negative. There was a peculiar atrophic condition of the skin and a condition of cyanosis on the peripheral parts. There was slight valvular disease of the heart. The diagnosis seemed to rest between rheumatism, a general trophoneurosis, and general syphilis. DR. B. SACHS said that he had been led to think of symmetrical muscular atrophies as such as occur after arthritic processes. It was not usual, however, to have them quite so symmetrical. He had had a suspicion that the case might be one of leprosy. DR. M. ALLEN STARR said that when traveling in Norway some years ago, he had seen a number of lepers, and had had his attention called to the existence of muscular atrophies in them. The peculiar appearance of the man's face had led him to think of leprosy without knowing Dr. Sachs' views on the case.

Acute Ataxia. DR. C. L. DANA read this paper, classifying acute ataxia as: (1) The acute bulbar and cerebellar ataxia; (2) acute spinal ataxia; and (3) acute peripheral ataxia due to multiple neuritis of the sensory type. He said up to recent times there had been no definite description of acute ataxia of spinal origin not due to tabes, and called special attention to 5 cases of nontabetic spinal ataxia reported in the paper.

NEW ENGLAND.

Yale Medical School.—Plans are being actively pushed to transfer this institution to Cedar Street, opposite the New Haven Hospital. The dispensary will first be transferred to Cedar Street.

Death Certificates.—A bill has been prepared by the Health Officers and the State Funeral Directors' Association of Connecticut to be submitted to the general assembly, providing that death certificates certifying only to the cause of death and the duration of the disease shall be returned by physicians within 36 hours after death.

CHICAGO AND WESTERN STATES.

Eye Disease.—A new infectious eye disease somewhat similar to "pink eye," noticed about a month ago in Chicago, is reported as epidemic there. It is attributed to the clouds of dust that have prevailed.

Illinois Epileptic Colony.—It has been decided to locate this State institution at Notch Cliff, near Elsah, in Jersey county. There are between 4,000 or 5,000 epileptics in Illinois. This will be one of the largest institutions in the State.

The Medical Society of City Hospital Alumni, St. Louis, Mo., held a meeting December 6, 1900. The following papers were read: Two unusual cases of denudation of the cranium with skin transplantation, by Dr. H. L. Nietert. 1. The female perineum. 2. Hernia, by Dr. F. Reder; Demonstration of fetal monstrosity, by Dr. H. S. Crossen; Some fracture cases, by Dr. N. W. Sharpe; Some cases of cardiac and arterial disease, by Dr. Elsworth Smith.

Military Surgery.—Dr. Nicholas Senn has been engaged by the University of Chicago to give a series of lectures upon Military Surgery. The series will begin next fall. This plan has been adopted since the Rush Medical College became affiliated with the university.

Prevention of Tuberculosis.—In Michigan, where methods of tuberculosis prevention have been pursued since 1891, the death-rate from tuberculosis has steadily diminished, and it can be ascribed to nothing but the efforts of the health authorities in this direction.

The Denver and Arapahoe Medical Society met November 27. An address on **Points in the diagnosis of iritis and glaucoma** was made by DR. EDWARD JACKSON. DR. JOHN S. MILLER read a paper on the **Present status of the subarachnoid injection of cocaine for anesthesia (Corning-Bier method)**. Cases were reported by DR. E. P. HERSHEY.

Donation to Rush Medical College.—A collection of books which represents the German surgical literature of the last 50 years has been donated to the library of this institution by Dr. Christian Fenger. This collection includes several thousand inaugural dissertations collected by Thiersch, the library of Professor Luecke, of Strasburg, and many rare books, such as Lebert's Atlas.

Against the Spitting Nuisance in St. Paul.—According to the *Medical Record* an ordinance was recently passed by both branches of the St. Paul city council and signed by the mayor, forbidding expectoration on the sidewalk under penalty of a fine of from \$1 to \$50, or imprisonment from 1 to 60 days. The duty of enforcing the law and arresting offenders against it devolves upon the police. The throwing of fruit skins and cigar stubs on the sidewalk is also forbidden. The ordinance was passed at the suggestion of the health commissioner.

A bill against quacks and holders of diplomas from bogus medical colleges is in preparation by Dr. W. B. Swan, the secretary of the Kansas State Board of Health. It is intended to submit it to the legislative committees of the medical societies in the State, and to the approval of the reputable physicians before introducing it into the legislature. It will provide for the examination and registration of physicians. All physicians now in the State will be obliged to register, and all those not holding diplomas from colleges of good repute will be obliged to take an examination.

Practises Medicine from his Cell.—Dr. O. R. Lacey is the only prisoner in Lake City jail in Colorado. He is serving a sentence for involuntary manslaughter, and while there is reported to have built up a good practice, as he is the only physician in the town. He eats and sleeps in the jail, and the county is obliged to pay all the expenses of his maintenance. He refused to give up part of the money he makes in his practice to the county, and a petition has been circulated asking the State Board of Pardons to release him. Dr. Lacey refuses to sign the petition, saying he is perfectly satisfied where he is.

The Lucy S. Ingals Prize Scholarship of Northwestern University Woman's Medical School, Chicago, Ill., has been awarded to Mrs. Emma B. Tucker and Miss Susan B. Tallman, for the session of 1900-1901. This scholarship, which was established by Dr. E. Fletcher Ingals, is conferred for excellent original work, or may be awarded as 2 half scholarships to a member of the second and a member of the third-year classes respectively, who shall attain the highest average in medical studies for that year. This prize is conferred only upon students possessing the degree of Bachelor of Science or Bachelor of Arts, or a degree of equal rank from a first-class university or college.

Municipal Lodging-House.—According to the *Medical News* the Commissioner of Health of Chicago announces that his forthcoming estimates will contain an item of \$20,000 for a municipal lodging-house, to be established in some rented building and to contain perhaps 300 beds. Such an institution might be designed, after the example of British cities, to serve the purpose of the ordinary common lodging-house which is run for profit, but evidently the proposal contemplates one which shall be of that specialized sort designed

to serve as an agency in dealing with the question of vagrancy. There is to be a medical sanitary inspector included in the staff and other officers with salaries to look after the health conditions of the enterprise.

The State Board of Health of Illinois will make in its forthcoming biennial report some important recommendations for legislation. Among them will be that a State sanatorium for tuberculous individuals be established after the plan that has been successfully followed in other States. The State Board of Charities will also be joined in its recommendation for provisions for the care of epileptics. Additional powers for township boards of health will also be asked. Under the present law these boards have no power to punish those who disobey the rules and regulations tending to check the spread of contagious diseases. The board will ask that a penalty be provided, and will further recommend that some provision be made for boards of health in counties not under township organization.

The College of Physicians and Surgeons of Oakland, Cal., has completed its reorganization, the incorporation papers have been filed, and the faculty selected. Sufficient funds have been subscribed to operate the school for the first year, and it is expected that it will be opened in time for the fall term. The following officers were elected: President, Dr. Frank L. Adams; secretary, Dr. Carl R. Krone; president of the faculty, Dr. J. S. Eastman. The faculty has been selected as follows: Dr. D. D. Crowley, professor of principles and practice of surgery and clinical surgery; Dr. F. L. Adams, clinical surgery; Dr. J. S. Eastman, professor of the principles and practice of medicine; Dr. Carl R. Krone, pathology; Dr. Hayward G. Thomas, ophthalmology and otology; Dr. S. H. Butreau, gynecology; Dr. W. F. B. Wakefield, clinical gynecology; Dr. R. T. Stratton, nervous diseases and cerebral surgery; Dr. Edward N. Ewer, obstetrics; Dr. W. S. Porter, surgical anatomy; Dr. J. L. Milton, anatomy; Dr. Oliver D. Hamlin, visceral anatomy.

Chicago Pathological Society.—At the regular meeting November 12, 1900, Dr. D. N. EISENDRATH demonstrated the following specimens: (1) **Adenoma of the liver.** The sections revealed a tumor sharply demarcated from the surrounding liver tissue, having a wavy outline with a yellowish outer and a whitish more fibrous inner portion. It was at first regarded as a carcinoma, but microscopically the structure was seen to be that of an adenoma. It was clearly revealed where the tumor tissue began and the normal parenchyma ended. There were many columns of new liver cells not arranged in the form of acini, separated from each other by trabeculas of connective tissue which seemed continuous with that of Glisson's capsule. The large size of the cells and the drops of fat contained in them were the most striking features. It is an open question whether to call this tumor an adenoma or a nodular hyperplasia. Orth thinks that if such a condition be called an adenoma it would be better to add hyperplastic to distinguish it from the tubular variety in which there are columns of cells, many having a distinct lumen. Both of these varieties may easily change into a carcinoma. (2) Specimens showing **relation of diseases of the gallbladder and intestines to infective cholangitis.** DR. HEKTOEN showed 2 rare cardiac anomalies: (1) **Congenital aorticopulmonary communication;** (2) **Communication between aorta and left ventricle** under the anterior aortic valve which was attached at both ends.

DR. MAXIMILIAN HERZOG read a paper of DR. GEORGE A. BOYE, of Baldwin, Kans., on **Sarcoma of the pancreas, with report of a new case.** In this and other cases cited in the discussion there was entire absence of glycosuria. Dr. Herzog said he believed that the pancreas furnishes a ferment which splits the sugar and forms from it alcohol and CO₂.

DR. LEO LOEB demonstrated specimens as follows: (1) **Carcinoma of sebaceous glands of a rat;** (2) **A Case of lymphosarcomatosis in a sheep;** (3) **Mitosis and cell divisions in different stages in eggs of guinea pigs' ovaries;** (4) **Specimen of a 16-pound tumor of the horn of the uterus of a sow.**

SOUTHERN STATES.

St. Vincent's Hospital, of Birmingham, Ala., with a capacity for 200 patients, was opened November 29.

Delaware Hospital for the Insane has had a bequest of \$1,000 from Elzy Wade, of Wilmington, lately deceased. He had been night watchman in the institution for a number of years.

The Galveston Storm.—The bodies of victims of this storm of 3 months ago are daily found under the debris and in swamps on the island and mainland. Last week the number amounted to 45.

Impure Milk.—The discovery that the milk furnished to the Charity Hospital of New Orleans was diluted led to the conviction and punishment of the dairyman, a daily analysis of the milk-supply and a strict inspection of the dairy and cows.

Tuscaloosa Hospital for the Insane is reported in a very overcrowded condition, with 1,500 inmates contained in a space intended for 1,000. Bills for an appropriation of \$25,000 to relieve this have been introduced into the State Senate and House of Representatives.

Suit for Damages.—Dr. George H. Noble, of Atlanta, Ga., has been sued by a patient upon whom he operated for \$10,000 damages. A piece of surgical gauze was left in her body and caused much pain until it was removed. The jury rendered a verdict for the defendant.

A negro hospital is to be erected in Winton-Salem, N. C. The building is to cost \$10,000, of which sum R. J. Reynolds, a white citizen, contributed \$5,000, while the negroes of the community raised the remainder. The Hospital will be operated in connection with the Slater Industrial School.

Georgia State Board of Health.—A bill has been introduced into the House of Representatives of Georgia which provides that the State Medical Society shall choose from its members 4 physicians and the governor shall appoint 5 other persons, one of whom shall be a sanitary engineer, to constitute the Board of Health of the State of Georgia.

Typhoid in Washington.—The Medical Association of the District of Columbia recently submitted to the Senate the report of a committee on the best plan for filtering Potomac water. Typhoid fever is reported to exist to an alarming extent in the Capital. The wells of the District have been closed, but the death-rate has increased rather than diminished.

Unsuitable Marriages.—At a meeting of the Tri-State Medical Society of Tennessee, Alabama, and Georgia, held recently in Chattanooga, measures were taken to obtain medical legislation in these three States to regulate or prevent the marriage of habitual criminals and drunkards, persons afflicted with incurable disease, and those addicted to the use of harmful drugs.

Richmond (Va.) News.—The city council is much agitated over the fact that there is no law restricting or forbidding the sale of spoiled meats, poultry or vegetables, and legislation looking to this end and the appointment of an inspector of milk may be expected. The city Board of Health has long and earnestly advocated these measures, but up to the present without effect.

The Cocain Habit.—The New Orleans police force has received an order from the Superintendent to use strict diligence in enforcing the ordinance relating to the use of cocain, as the constant increase in its use has become so serious as to menace the public health.

The physicians of Birmingham, Alabama, are the instigators of a bill about to be introduced in the legislature, especially directed against cocain, but prohibiting the indiscriminate sale of deadly drugs.

Maryland Public Health Association.—At a recent meeting the subject of how to combat tuberculosis was discussed. Dr. Joseph E. Gichner, of Baltimore, who has for years made a study of this subject, read an interesting paper. He believes that there are 10,000 cases of the disease in Baltimore. During the last 6 years the deaths from the disease in that city have ranged from 974 to 1141 annually.

He also showed that public institutions in and about Baltimore have a capacity for receiving and treating 86 patients. **The Perils of Culture** was the title of a paper read by Dr. A. K. Bond, of Baltimore.

The Orleans Parish Medical Society held a meeting November 24. DR. S. P. DELAUF read a paper on **Ligation of the innominate artery for aneurysm**. (This will be published in a future number of the JOURNAL.) DR. A. W. DEROALDES demonstrated the use of a chair, devised by Dr. French, of Brooklyn, for operations in the sitting posture. DR. GORDON KING read a paper on the **Asch operation for correction of deviated nasal septum**, reporting a series of successful cases.

Plan to Care for Indigent Sick.—The Board of Supervisors of Charities in Baltimore at a recent meeting announced the perfection of a plan for the care of the city's indigent sick, which will tend to simplify the work and reduce it to a system. This plan means the selection of certain general hospitals and dispensaries, to which will be intrusted the care and attention of the helpless sick. The hospitals selected are the Baltimore City Hospital, University of Maryland, Maryland General, St. Joseph's, and the Maryland Homeopathic Hospital. The dispensaries chosen are the Baltimore General, Southern, Northeastern, Eastern, Woman's Medical College Dispensary, Southern Homeopathic Medical College and Hospital, and the Baltimore Eye, Ear, and Throat Charity Hospital. Tuberculous patients or incipient nervous cases will be sent for special treatment to St. Agnes' Hospital, or tuberculous individuals to the Hospital for Consumptives of Maryland. Deformed children may be sent to the special Hospital for Crippled and Deformed Children.

The Johns Hopkins Hospital Medical Society.—At a meeting held November 19, 1900, DR. MARSHALL exhibited the following pathologic specimens: (1) **Ulcerative endocarditis**, (2) **Cystic kidney and liver**. The heart specimen exhibited was obtained from a patient admitted to the hospital September 6, in whose case the clinical diagnosis of acute endocarditis with adherent pericardium and evidences of former heart lesions was made. It demonstrated these lesions accurately. Old patches of thickening on the mitral valve and its chordae tendinae were found. In addition to the valvular lesions there was a general hypertrophy of the entire heart and the pericardium was closely adherent to its whole surface. Dr. Marshall believed that it was impossible to determine that any particular organism would always produce a certain lesion, sometimes the supposedly milder bacteria produced very severe lesions and vice versa. Recent writers state that *Staphylococcus aureus* is likely to produce the ulcerative form of endocarditis, while the streptococcus and pneumococcus are more likely to result in the production of widespread vegetations. The kidney and liver specimens were obtained at an autopsy upon a Bay View patient whose history was not well known. He had been admitted to the hospital suffering principally from a severe diarrhea. At the autopsy it was found that the terminal affection had been an enteritis and with this an endocarditis. The patient, however, proved to be a veritable pathologic museum in himself, for in addition to the troubles above mentioned he presented evidences of an arthritis, a healed fracture of the humerus, tuberculosis, bronchial pneumonia, cholelithiasis, a carcinoma at the fundus of the gallbladder, with metastases in the liver, and a congenital cystic kidney on one side.

The mechanism of a new hemoglobinometer was demonstrated by DR. DARE, of Philadelphia. See PHILADELPHIA MEDICAL JOURNAL, September 22, 1900, p. 55.

DR. RUSK exhibited **Congenital absence of the pectoralis major and minor**. The patient had been admitted to the gynecologic service for operation and in the course of a physical examination this anatomic abnormality, which had not given rise to any trouble, was discovered. No evidence of either pectoral muscle could be obtained either by palpation or electric stimulation.

CANADA.

The Insane of Ontario.—The Ontario government has recently been receiving some severe criticism for failing

to provide proper and full accommodation for the lunatics who are confined in the common gaols of the province. Toronto especially is taking active steps to have this abuse immediately removed. In the gaol of that city not less than 49 insane people are confined like other criminals, awaiting transference to government asylums, but as there is no accommodation for them, they continue on in their present quarters. The medical health officer, Dr. Sheard, and Dr. Richardson, the gaol surgeon, have been appointed a committee to lay this matter before the provincial secretary, seeking to have the wrong remedied. The government claims that it is hurrying on the work at the old Victoria College at Cobourg, which, when completed, will accommodate 200 patients.—[*Journal American Medical Association*.]

MISCELLANY.

Dr. Ramiro Diaz, a graduate of Nashville, Tennessee, has been appointed to the medical corps of the Mexican army and navy with the rank of captain. He is also a graduate of a special military medical school in Mexico.

Obituary.—EDGAR MARTIN VARY, of Kingston, N. Y., December 5.—GEORGE B. BANKS, of Huntingdon, L. I., December 4.—ROBERT R. WASHBURN, of Waldron, Ind., November 11.—C. F. HARTER, of Akron, Ind., November 19.—FREDERICK W. FLEIBEL, of Philadelphia, December 6, aged 66.—SARAH E. SHERMAN, of Salem, Mass., December 6, aged 55.—WALKER R. STEPHEN, of Reading, November 27, aged 49.—CLARENCE E. FOSTER, of Honesdale, Pa., November 26, aged 43.—FRANK S. HARKER, of Richmond, Va., December 7.—EDWARD A. SMITH, of New York, December 10, aged 71.—E. A. MERRIFIELD, of St. Louis, December 6, aged 75.—JOSEPH T. SHOEMAKER, of Philadelphia, December 6, aged 62.

Emergency Ration Test.—The final test of the emergency rations was completed recently by the experimental board of the War Department, and the troopers have returned to Fort Reno. The march was made into the Caddo and Wichita Indian reservations, and, as before, 50 troopers were in command of Capts. Fountain and Foster. The last ration tested was prepared by these 2 officers, under the instructions of the War Department, and the board has come to the conclusion that its own rations are the best. Two tests demonstrated that the ration will sustain the soldier in good health and strength for a period of 5 days, and that, instead of its becoming unpalatable on the last day, it becomes more appetizing. The ration compounded by 2 packing companies has a nauseating effect.

An Unnamed Hero.—The Board of Medical Officers which has been studying yellow fever in Cuba has not thought it worth while to mention in its report the name of a young American civilian who allowed himself to be infected with yellow fever by means of a mosquito bite and died from the effect. Two physicians who made the same heroic experiment also contracted the disease. One died and the other recovered. The former was Dr. Jesse W. Lazear, the latter Dr. James Carroll. Their names are given, and very properly so, but the name of the heroic comrade should be preserved also. All three were engaged in one of science's forlorn hopes, and their courage was of a kind that cannot be excelled on the battlefield. Their fame should be handed down to posterity.—[*Philadelphia Ledger*.]

The Röntgen Society of America held its first regular meeting at the Grand Central Palace, New York, December 13 and 14, 1900. Papers were read bearing directly on the application of skiagraphy to surgical, medical, and dental practice, and an exhibition was given of apparatus and skiagraphic plates and lantern slides. The president of the society is Dr. Heber Roberts, of St. Louis, editor of the *X-Ray Journal*, to whose efforts the organization chiefly owes its existence, and the other officers are:—Vice-presidents, Dr. J. P. Girdwood, of Montreal, and Dr. H. P. Bender, of Brooklyn; secretary and treasurer, Dr. J. Rudis-Jicinsky, of Cedar Rapids, Iowa, assisted by Dr. Carl Beck, of New York. The sectional work of the society is delegated to committees whose chairmen are:—Dr. Mهران K. Kassabian, Philadelphia, publication; Dr. Wm. H. King, New York, necrology; Dr. Richard H. Cunningham, New York, conduct; Dr. Carl Beck, New York, revision of the constitution.

Health of Troops in the Philippines.—Surgeon-General George M. Sternberg, U. S. Army, has received the following letter from Major L. B. Grandy, surgeon of the 35th Infantry, stationed at Bailinag, P. I.: "The health of our troops continues good in spite of irresponsible reports to the American newspapers to the contrary. This at least is a very healthful portion of the island of Luzon, and barring certain skin lesions incident to a soldier's life in this climate, I don't think the sickness among the troops has exceeded that among the volunteers in the States 2 years ago. Including the killed in action, there have been fewer deaths in the 35th Infantry in a year's service than in the regiment that I was connected with 2 years ago in 8 months. I think it likely that this is substantially true of other commands over here, excepting perhaps the killed in action."—[*Army and Navy Register*.]

Typhoid Fever in the Army.—Surgeon-General Sternberg has made public a report upon the origin and spread of typhoid fever in the United States military camps during the Spanish war of 1898, and calls attention to the vast amount of work the medical corps had to perform owing to the tremendous increase of the army in the field and the prevalence of typhoid, 20,000 cases of this disease having appeared among the troops encamped within the limits of the United States, from May until September, 1898. Many commands during the war were unwisely located, the space allotted to regiments was, in some instances, entirely inadequate, and many regiments were allowed to remain on one site too long. This and the lack of proper facilities for disposing of the excretions of the human body were no doubt in a large measure responsible for the prevalence of the fevers in camps. Infected water was found to be an unimportant factor in the spread of typhoid in the national encampments of 1898. The part played by flies in the dissemination of germs of the disease, however, was plainly evident.

Hypnotism.—Solicited articles written by 37 men, including representatives of the faculties of Harvard, Yale, Princeton, Pennsylvania, and Berlin, were published by the New York State Publishing Company, of Rochester, N. Y., in the form of a book with the title "Hypnotism and Hypnotic Suggestions." The authors were surprised and indignant to learn almost as soon as they had received copies of the book that these articles had been applied to another use. Incorporated with others they formed a second volume prepared for free distribution by the American College of Science, an institution of Philadelphia which advertises to teach hypnotism to any ordinarily intelligent person, and in proof of its ability, and to afford evidence of its reality and of its dignity as a science invokes the authorities of the great universities who would not sanction an imaginary science nor endorse misstatements. The president of the American College of Science asserts that he purchased the right to use the papers from the New York State Publishing Company, and the grievance cannot be charged against his institution.

Smallpox still exists in many parts of the United States. At Manchester, N. H., 8 new cases have been reported. The city pest house is overcrowded and the health officers are undecided as to what to do with future cases. There are 400 cases in Winona, Minn., and to prevent its spread the Board of Health has closed 2 public schools and ordered the street car company to stop its cars at the boundary of the infected district. The disease is still epidemic at Decatur and other small towns near the Omaha Indian Reservation. Many deaths and 250 cases are reported. The disease has spread to Iowa, where the power of the State Board of Health has been invoked, and the Nebraska State Board will establish quarantine. At Perigue, Mo., several cases are reported. The place has been quarantined, the schools closed and no trains stop at this point. Numerous cases are reported along the Yukon in Alaska from Dawson to the lakes. The U. S. Quarantine officers believe that the disease will be epidemic in Alaska for many months. At Whitesboro, Texas, 30 cases have been reported, with no deaths. At Erin, Tenn., 12 cases are reported among the negroes; a pest-house will soon be built. A mild form of the disease is reported among the Kiowa, Comanche and Wichita Indians in the Indian Territory. In Central and Southern Texas the disease is epidemic.

In Travis County many thousands of dollars have been expended in maintaining pest camps and enforcing quarantine measures. The disease is confined principally to negroes. In Ashland, Wis., there are 22 cases. No deaths are reported. Kansas City physicians fear a serious outbreak this winter. New cases are reported daily. Last winter the epidemic cost the city nearly \$70,000. In the boroughs of Manhattan and the Bronx, New York, 46 cases have been reported recently. There are 24 smallpox patients in the Willard Parker Hospital, New York City. Vaccination measures are being enforced. The Council of Yukon, Alaska, has passed an ordinance requiring all persons in Yukon Territory to be vaccinated. This order affects 15,000 persons.

The Pan-American Medical Congress.—The next meeting of this Congress, to be held at Havana from February 5 to 9, 1901, promises to be a successful one, and a large attendance is expected. The general officers are: President, Dr. William Pepper; treasurer, Dr. A. Van Der Veer; secretary, Dr. C. A. L. Reed; chairman committee on transportation, Dr. H. L. E. Johnson; associate secretary, Dr. Ramon Guitéras. It is sincerely hoped that the United States will be well represented, and that the program of the Section on Medicine will be a creditable one. The titles of papers intended for this section, together with the name and address of the author, should be sent as soon as possible to the secretary of the Congress, Dr. Tomas V. Coronado, Prado 105, Havana, Cuba, and it is especially desired that a short abstract of the paper should also be prepared and mailed at the same time. For further particulars, address Dr. Judson Daland, 307 South Eighteenth Street, Philadelphia, secretary of the Section on Medicine. Communications relative to the Section on Gynecology and Abdominal Surgery should be addressed to the section secretary, Dr. Henry P. Newman, 100 Washington street, Chicago.

The following is the program of the different sections:

PROGRAM OF SECTIONS.

1. **GENERAL MEDICINE.**—President, Dr. Carlos Finaly; secretaries, Dr. Damaso Laine, Dr. Federico Grande Rossi, Dr. Antonio Diaz Albertini, Dr. Judson Daland, 317 S. 18th St., Philadelphia.
2. **GENERAL SURGERY.**—President, Dr. Tomas Plasencia; secretaries, Dr. Jose Varela Zequeira, Dr. Gustavo Duplessis, Dr. Julio Ortiz y Cano, Dr. Francisco Dominguez, Dr. W. P. Nicholson, Prudential Building, Atlanta, Ga.; Dr. John Ridlon, 103 State St., Chicago, Ill.; Dr. Duncan Eve, 700 Church St., Nashville, Tenn.
3. **MILITARY MEDICINE AND SURGERY.**—President, Dr. Eugene Sancho Agramonte; secretaries, Dr. Nicholas Alverti, Dr. Matias Duque, Dr. Jose R. Anciano, Major Jefferson Kean, surgeon, U. S. A., Quemados, Cuba.
4. **OBSTETRICS.**—President, Dr. Eusebio Hernandez; secretaries, Dr. Ernesto Aragon, Dr. Rafael Weis, Dr. Jorge Le Roy, Dr. Gustave Zink, 13 Garfield Pl., Cincinnati, O.
5. **GYNECOLOGY AND ABDOMINAL SURGERY.**—President, Dr. Gabriel Casuso; secretaries, Dr. Ramon Palacios, Dr. Pedro Suarez del Solar, Dr. Fernandez Mendez Capot, Dr. Enrique Fortun, Dr. Enrique Nunez, Dr. H. P. Newman, 103 State St., Chicago, Ill.
6. **THERAPEUTICS.**—President, Dr. Raimundo Castro; secretaries, Dr. A. Perez Miro, Dr. Gonzales O'Brien, Dr. Francisco Portela, Dr. Hobart A. Hare, 222 S. 15th St., Philadelphia.
7. **ANATOMY.**—President, Dr. Federico Horsman; secretaries, Dr. Jose A. Fresno, Dr. Cecilio Reol, Dr. Gabriel Landa, Dr. A. D. Bevan, 100 State St., Chicago, Ill.
8. **PHYSIOLOGY.**—President, Dr. M. Sanchez Toledo; secretaries, Dr. Jose de Carlos y Ferrall, Dr. Jaun B. Fuentes, Dr. Manuel Altuna, Dr. A. P. Brubaker, 105 W. 34th St., Philadelphia.
9. **PEDIATRICS.**—President, Dr. Joaquin L. Duena, secretaries, Dr. Gonzalo Arostegui, Dr. Ernesto Edelman, Dr. Alejandro Neyra, Dr. I. N. Love, 49 W. 44th St., New York City.
10. **OPHTHALMOLOGY.**—President, Dr. Enrique Lopez, secretaries, Dr. Jorge L. Dehogues, Dr. Carlos Finley (hijo), Dr. Manuel Masferrol, Dr. John E. Weeks, 40 E. 57th St., New York City.
11. **LARYNGOLOGY, RHINOLOGY AND OTOTOLOGY.**—President, Dr. Carlos Desvernine; secretaries, Dr. Emilio Martinez, Dr. G. Hudson Makuen, 1419 Walnut St., Philadelphia, Pa.; Dr. James F. McKernon, 62 W. 52d St., New York City.
12. **DERMATOLOGY AND SYPHILOGRAPHY.**—President, Dr. Henry Robelin; secretary, Dr. A. Ravogli, 5 Garfield Place, Cincinnati, O.
13. **GENERAL HYGIENE AND DEMOGRAPHY.**—President, Dr. Vincente de la Guardia; secretaries, Dr. Enrique B. Barnett, Dr. Santiago Sijar, Dr. Eugenio Cuesta, Dr. Jose Antonio Lopez, Dr. Felipe Canizares, Dr. Alvah H. Doty, Quarantine Station, Staten Island, New York City.
14. **MARINE HYGIENE AND QUARANTINE.**—President, Dr. Luis Cowley; secretaries, Dr. R. O. Marcour, Dr. Federic Torralbas, Dr. R. M. Woodward, surgeon, M. H. S., Washington D. C.

15. MEDICAL PEDAGOGY.—President, Dr. Manuel Delfin; secretaries, Dr. Francisco Vildowola, Dr. Aristides Agramonte, Dr. Otis K. Newell, 13 Central Park, West, New York City.

16. MENTAL AND NERVOUS DISEASES.—President, Dr. Gustavo Lopez; secretaries, Dr. Jose A. Malverti, Dr. Aristides Mestro, Dr. Rafael Perez Vento, Dr. Chas. P. Hughes, 3557 Olive St., St. Louis, Mo.

17. DENTAL SURGERY.—President, Dr. Erastus Wilson; secretaries, Dr. Adolfo Betancourt, Dr. J. R. Madan, Dr. Eugene S. Talbot, Columbus Memorial Building, Chicago, Ill.

18. BACTERIOLOGY.—President, Dr. Juan N. Davalos; secretary, Dr. G. Garcia Rijo.

19. MEDICAL JURISPRUDENCE.—President, Dr. Jose M. Cespedes; secretaries, Dr. Juan Gomez de la Naza, Dr. Ernesto Sarra, Dr. Alvarez Ortiz.

Health-Reports.—The following cases of smallpox, yellow fever, and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, for the week ended December 8, 1900.

SMALLPOX—UNITED STATES.

DISTRICT OF	CASES.	DEATHS.

Changes in the Medical Corps of the U. S. Army, for the week ended December 8, 1900:

WILSON, COMPTON, acting assistant surgeon, is relieved from duty at Aibonito, P. R. and will proceed to Washington Barracks and

report by letter to the Surgeon-General of the Army for further orders.

EBERLE, H. A., acting assistant surgeon, is relieved from duty at the subpost of Aguadilla, P. R., and will take station at the subpost of Aibonito, P. R., for duty.

CUTLIFFE, WILLIAM O., acting assistant surgeon, will be relieved from duty at Mayaguez, P. R., and will proceed to the United States and report by letter to the Surgeon General of the Army.

HAVARD, Major VALERY, surgeon, now on leave of absence at Bridgeport, Conn., will proceed to Washington, D. C., and report to the Surgeon-General of the Army for consultation on business pertaining to the medical department in Cuba, and upon the completion thereof will return to Bridgeport, Conn.

HYSELL, Major JAMES H., surgeon, is honorably discharged from the service, to take effect December 19, his services being no longer required.

FISCHER, CHARLES H., acting assistant surgeon, is relieved from duty at Fort Apache, and will proceed to Washington, D. C., and report to the Surgeon-General of the Army for annulment of contract.

THORP, CHARLES W., acting assistant surgeon, will proceed from Denver, Colo., to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, and upon arrival at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

WHITE, J. SAMUEL, acting assistant surgeon, will proceed from Mannheim, Pa., to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, and upon arrival at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

LYSTER, First Lieutenant THEODORE C., assistant surgeon, leave of absence granted November 3, is extended 10 days.

HAVARD, Major VALERY, surgeon, leave of absence granted November 12 is extended 14 days.

COONEY, DANIEL C., acting assistant surgeon, orders relating to, of November 10, are revoked.

COONEY, DANIEL C., acting assistant surgeon, is granted leave of absence for 1 month.

GERAHTY, ROBERT F., hospital steward, Army General Hospital, Presidio, is relieved from further duty in the division of the Philippines and will be sent to San Diego Barracks for duty, to relieve Hospital Steward Herbert Thompson.

THOMPSON, HERBERT, hospital steward, will be sent to Manila, P. I., for assignment to duty.

Changes in the U. S. Marine-Hospital Service, for the week ended December 6, 1900:

COFER, L. E., assistant surgeon, commissioned as passed assistant surgeon. November 23.

CARTER, H. R., surgeon, granted extension of leave of absence for 15 days from December 1, on account of sickness. November 30.

PECKHAM, C. T., surgeon, granted leave of absence for 2 months from December 17. November 30.

BROOKS, S. D., surgeon, granted leave of absence for 5 days from December 11. December 6.

McINTOSH, W. P., surgeon, to proceed to Perry, Ga., for special temporary duty. December 1.

YOUNG, G. B., passed assistant surgeon, granted leave of absence for 3 days. November 30.

WICKES, H. W., passed assistant surgeon, granted extension of leave of absence for 10 days. December 3.

COFER, L. E., passed assistant surgeon, upon being relieved from duty at Los Angeles, Cal., to proceed to Honolulu, H. I., and report to Surgeon D. A. Carmichael for duty. December 1.

HASTINGS, HILL, assistant surgeon, relieved from duty at the Columbia River Quarantine, Astoria, Oreg., and directed to proceed to Los Angeles, Cal., and assume command of the service, relieving Passed Assistant Surgeon Cofer. December 1.

PARKER, H. B., assistant surgeon, to proceed to Magnolia and Fayette, Miss., and St. Joseph, La., for special temporary duty. December 1.

VOGEL, C. W., assistant surgeon, upon being relieved from duty at the San Francisco Quarantine, to proceed to San Francisco, Cal., and report to medical officer in command for duty and assignment to quarters. December 1.

Changes in the Medical Corps of the U. S. Navy, for the week ended December 8, 1900.

BLAKEMAN, R. S., passed assistant surgeon, ordered to be examined December 10, at Washington, D. C., for retirement, and thence home to wait orders.

DUNBAR, A. W., passed assistant surgeon, ordered to the "Vermont" for duty with the crew of the "Wisconsin" revoked; ordered to duty at Naval Hospital, Mare Island, December 14.

GARTON, W. M., assistant surgeon, ordered to the Washington Navy Yard. December 5.

BIDDLE, C., surgeon, ordered to the Naval Hospital, Norfolk, Va., for temporary duty.

GIAOW, E. J., assistant surgeon, detached from the "Monadnock" and ordered to the "Culgoa."

COWAN, J., pharmacist, detached from the "Monadnock" and ordered to the "Culgoa," and to additional duty at the Cavite Naval Station.

Foreign News and Notes.

GREAT BRITAIN.

The Office of Apothecary to the Union has been abolished by the Local Government Board of Ireland and a qualified assistant medical officer substituted, whose duties shall include the compounding of the medicines.

The Lewis Epileptic Colony.—Nearly £100,000 have been given by the David Lewis trustees for the establishment of an epileptic colony in Cheshire, and 400 acres have been purchased at Warford for the purpose. The patients will live in detached buildings accommodating 20 or 24 inmates and healthy occupation will be provided on the farm.

The Staff of the Irish Hospital.—Sir William Thomson and other members of the staff lately returned from South Africa were welcomed with a banquet on November 24 by the President and Fellows at the Royal College of Surgeons in Ireland. Sir William Thomson in a speech alluded to the great difficulties of transport and emphasized the fact that the Irish Hospital was the only civil hospital in South Africa that was able to move independently.

Cancer in London.—According to the *Medical News*, London medical science is being directed toward the elucidation of the problem of the causation of cancer. A cancer research laboratory has just been opened at the Middlesex Hospital, to be entirely devoted to the systematic investigation of cancer. The Middlesex Hospital is alone among the great London hospitals in admitting inoperable cases of disease, where the only hope is that death may come without much more pain. Some 60 of these hopeless cases will be now under close scientific scrutiny.

An Inquiry Concerning Sanity.—A case requiring investigation recently laid before the Royal Courts of Justice, is that of a widow lady of independent means who was kept at Wyke House Private Asylum, Isleworth, from January, 1899, to September last. She herself dates her recovery of reason from 7 months after admission. On March 20, 1900, in accordance with her instructions, her solicitor refused to pay for her maintenance at the asylum in order that a legal inquiry into her mental condition might be brought up. After a patient trial the jury found that she was capable of managing herself and her own affairs.

Antiplague Serum.—A member of the Royal College of Physicians, whose name is not given, warns the public against giving credence to reports of the efficacy of antiplague (Pasteur) serum and quotes from this year's official report on the plague in Bombay: "So far as information is obtainable of M. Yersin's results and those of other doctors, French and Russian, who have tried it, it has failed to influence favorably the mortality among those attacked." Favorable results were reported from Oporto where it was tried, but the writer asserts that he was present and no scientific value whatever attaches to them.

The British Congress of Tuberculosis is announced to open July 22, 1901. Invitations will be issued to foreign governments and universities, as well as to municipalities, to nominate delegates. The Congress will transact its business in 4 sections—medicine, pathology, veterinary medicine, and State medicine, which, as at present arranged, will meet on the mornings of July 23, 24, 25 and 26. It is proposed that there should be in the afternoons general meetings of the whole Congress, to be addressed by distinguished representatives of pathology, medicine, and veterinary medicine. The fee of £1 for all members of the Congress will entitle them to attend all the meetings, and to a copy of the *Transactions*. Particulars can be obtained from the General Secretary, Malcolm Morris, 20 Hanover Square, London, W.

Röntgen Rays Cause Burn.—The coroner of Hastings has made inquiry into the cause of death of a woman who fell last March and fractured the neck of the femur. At the suggestion of the physician called and with the consent of the patient a local photographer was engaged to make a skiagram of the injury. The apparatus was not of the latest

pattern and a long exposure was necessary. The first exposure of 2 hours was not satisfactory, and after 20 days a second exposure of 2 hours and 10 minutes was followed by inflammation and, as far as can be made out, by ulceration of the abdominal wall. The jury returned a verdict to the effect that death was due to shock and exhaustion following the accident and the effects of the x-rays on a weakened system, and no blame attached either to the medical man or the photographer.

Arsenical Beer.—The *Lancet*, in discussing the beer-poisoning cases in Manchester and other places, says: "We are pleased to learn that definite steps are being taken to stop the sale of arsenical beer. We have examined a specimen of invert sugar (a variety of sugar consisting of a mixture of dextrose and levulose, found naturally in fruits and produced artificially by the inversion of cane sugar) used in brewing, and found that it contained 3 grains of arsenious acid per pound. Hence a glass of beer might contain one-fifth of a grain of arsenic. A careful examination of the form in which arsenic existed in this sugar shows that it was mostly arsenious acid in small quantities. Arsenic acid was also detected." It appeals to the Government to define beer as a liquid brewed exclusively from barley, malt and hops, so that beer made from substitutes of these ingredients will have to be called by another name. A report made by the authorities in France in 1878 said that glucose used in brewing contained arsenic. The use of substitutes for the regular ingredients is prohibited absolutely in Germany.

The Pasteur Institute in London, for which Lord Iveagh gave £250,000, has not advanced the diagnosis and prophylaxis of hydrophobia according to a letter addressed by Dr. Howell Rees, of Glan-Garnet, Wales. The idea was that when a dog suspected of rabies was killed its head should be sent to the Board of Agriculture in order that it might undergo expert examination, and no case of rabies should be enrolled except on the report of the expert. Dr. Rees complains that when, in the discharge of his duty in September last, he sent the head of a dog which had bitten 2 persons the day before, and waiting 2 weeks for a report, he had been obliged to send the patients to the Paris Institute. He wrote again to the Board of Agriculture and received a reply to the effect that "from the description of the case of suspected rabies furnished to the Board by their inspectors (who had never seen the dog) the chief veterinary officer of the Board recommended that it should be accepted as a case of rabies, and it, therefore, became unnecessary to carry out the inoculation experiment."

Defensive Measures Against Plague.—Professor Calmette, of the Pasteur Institute at Lille, has been lecturing in London before the members of the Royal Colleges of Physicians and Surgeons, upon defensive measures against the plague. He said that although it was now impossible to deny that the use of antiplague serum was an excellent means for preventing the propagation of the disease in an infected center, the short duration of the immunity it bestowed, together with the material difficulty of procuring it in sufficient quantity to vaccinate and revaccinate a large number of individuals, rendered it necessary to seek a practical means for giving to men an active immunity by means of the plague virus itself. While acknowledging the great value of Dr. Haffkine's plague cultures, he said that his method was open to some grave objections. Thus during the period of immunization with the heated cultures, animals were extremely susceptible to very minute doses of plague virus; hence if any one were to undergo the Haffkine inoculation during the incubating period of a slight attack of plague, the attack would be greatly aggravated, and would probably be fatal. Moreover, no good method existed for comparing different vaccines prepared according to Haffkine's process. During the past year, he said he had been carrying on experiments with a view to obviating the principal objections, and he described a process by which he obtained dried plague bacilli free from every trace of toxin, the injection of which produced no grave local reaction. When he wished to vaccinate animals he took a quantity of these microbes, apportioned by weight according to the kind of animal, suspended in a fixed quantity of sterilized salt water, and injected it under the skin or into the veins. If these dried germs, diluted with salt water, were mixed with

the proper amount of antiplague serum, the injection conferred at one and the same time an immediate passive immunity and an active immunity which took longer to set up, but prolonged the period of resistance to the infection. The superiority of this method consisted in the precision of its experimental effects and the facility with which it could be anywhere used and controlled. He said that great care ought to be taken to prevent the escape of even a single rat from a suspected ship, and declared that all ships communicating with plague-infected ports ought to be supplied with antiplague serum to be used whenever a case shall appear on board.

CONTINENTAL EUROPE.

Iced Chloroform.—It is stated that this anesthetic has been used in 14,000 cases in Würzburg, Bavaria, without any ill results. Rapidity of action, comparative freedom from danger, and absence of nausea and depression are the advantages claimed for this preparation.

The Use of Absinthe.—The constant increase in the consumption of absinthe in France, which is now estimated at 10,000,000 liters annually, called forth a resolution, moved by M. Vaillant in the Chamber of Deputies, Paris, December 10, prohibiting the manufacture and sale of all alcoholic liquors pronounced dangerous by the Academy of Medicine. It was unanimously passed.

Foot and Mouth Disease.—The American Consul at Bordeaux has informed the State Department that this disease prevails among the cattle in Charente and neighboring departments in France, and that the introduction of cattle, sheep, hogs, and goats from the infected departments into the Gironde is forbidden. There is no exportation of these animals themselves from Bordeaux to the United States, says the Consul, but their hides come to this country in considerable quantities.

Housing the poor in Berlin has become a serious problem owing to the absence of suitable dwellings for the constantly increasing population. The distress of those crowded out is so great that the authorities propose to build rooms for the express purpose of storing the goods of these unfortunates who earn money and have furniture, though they are unable to find a roof. The building trade prefers to erect huge edifices, the rents of which are beyond persons of small means, and yet the Berlin municipality spends yearly about 4,000,000 sterling for the poor and homeless.

Women Physicians in Austria.—According to a decree of the Austrian Minister of Public Instruction, women who have successfully passed an examination of maturity will henceforth be admitted to the study of medicine and the obtention of a doctor's degree in Austrian universities. Heretofore they were obliged to make their studies and obtain a degree in foreign universities, which was recognized by any Austrian university. Where certain professors object to the admission of female hearers to their lectures, exceptions were granted by the competent authorities to enable applicants to accomplish their purpose. A second decree permits women to conduct a pharmacy, with the sanction of the ministry in each special case.

Measures Against Tuberculosis.—The German Department of the Interior has issued a set of instructions conveying compulsory precautions to be taken against the spread of tuberculosis in the empire, a copy of which has been sent to the Department of State by United States Consul Monaghan at Chemnitz. The instructions consist of 7 articles, providing that doctors, under all circumstances where their patients have lung or larynx tuberculosis, must give written notice to the police as soon as the case in question has been diagnosed; that immediately after the death of a person from this form of the disease the room he used and his effects must be thoroughly disinfected; that professional women who lay out the dead must report at once in writing to the police authorities whether the disease was of the lungs or larynx; and that keepers of hotels, lodging-houses, asylums, or other public institutions, shall report immediately the appearance of the disease in the establishment under their control. Non-compliance with these

regulations is subject to a fine of \$35.70 or 6 weeks' imprisonment.—[*N. Y. Evening Post.*]

Typhoid in Paris.—The recent increase in the number of typhoid cases in Paris has directed attention to the quality of the water in that city. The subject has been the cause of a lively discussion in the Council of Hygiene. It is reported that polluted Seine water had been mixed with the drinking water, and official investigation proves this to be true. The Charonne reservoir, from which the Paris drinking water is derived, is divided into two parts, one of them containing ordinary Seine water, and the other water from the filtering beds at Ivry. These filtering beds, constructed in opposition to the opinions of the committees of hygiene, are composed of successive layers of gravel gradually becoming finer, and act merely as strainers. They do not really purify the water, which after passing through them retains from 60 to 70% of its organic matter, and about 5% of its microbes. The intake of this water at Ivry is near factories, and the outlets of sewers. The water, therefore, as it comes from the filters, cannot be regarded as fit for drinking, and it is this water which, after arriving at the Charonne reservoir, has been conveyed to the reservoir at Ménilmontant, and mixed with the wholesome water of the Dhuys. This proceeding went on for 4 months. It was at that period that typhoid fever attained its maximum in Paris. When the matter was discovered the engineers discontinued mixing the water and typhoid fever immediately declined, for in 12 days the mortality fell from 18 to 7 deaths per week.

Charged with Physiologic Vivisection.—According to the *British Medical Journal* Professor Pflüger, of Bonn, has made against the eminent Berlin surgeon, Professor Israel, and against Professor Immanuel Munk, the physiologist, the accusation that they have "undertaken physiologic vivisection on a human being." The indictment is as follows: In the year 1889 a girl suffering from elephantiasis of the left leg was an inmate of the Berlin Jewish Hospital, of which Professor Israel is Director and Chief Surgeon. On her leg was an opening from which lymph flowed continuously. It seemed of interest to Professor Munk and to Dr. A. Rosenstein to examine the influence of different kinds of food on the composition of the lymph. "Thus, Professor Israel," writes Pflüger, "abandoned the poor girl to Messrs I. Munk and Rosenstein for purposes of research." And he details his charges as follows: "Although the patient could be laid in such a position that the discharge and loss of fluid ceased, or was greatly diminished, chyle was drawn off from her by the liter, and blood taken, after she had been induced either to swallow disgusting chemical preparations, or else to fast for some length of time." Professor Israel recently published his answer to Pflüger's charge. He says: I repudiate with the fullest energy Professor Pflüger's characterization of the examinations as "vivisection," and his unheard of accusation, that the patient had been abused "like a dog for physiologic purposes." Pflüger's charges bear on 4 points: (1) Drawing off chyle by the liter; (2) exhibition of disgusting chemical preparations; (3) the long fasts; (4) drawing off blood for analysis. As regards charge 1, the truth is, that no chyle at all was drawn off, but during the period of the researches the chyle that usually flowed into the bandages was collected. It was necessary to allow the patient to get up and take exercise, and the lymph that flowed during these periods was used for purposes of analysis. The patient was exceptionally well nourished and very robust, and suffered so little from the loss of fluid that she looked healthier during the period of exercise with flowing fistula than while kept in bed and the fistula dry. The preparations given the patient were chiefly medicaments, for instance, lipanine and similar oils and fats, charcoal, etc. With regard to the third charge, the fasts for experimental purposes, it is true that during the period of research the patient twice fasted 9 hours, once 18 hours, and once a whole day, the effects being counteracted by exceptionally nourishing food. The "drawing off" of blood consisted in 4 applications of a cupping glass at intervals. Professor Israel winds up with the words: "Without expressing an opinion on the repeated abstinence from food, and applications of the cupping glass, which occurred without my knowledge, I can only testify that they did not in any way affect the patient's health, but that, on the contrary, she was afterwards dismissed from the hospital in florid health, with the fistula cured."

MISCELLANY.

Typhoid.—The German losses in China from typhoid and climatic diseases generally continue large, despite official denials. The official dispatches themselves are proof of the inroads of the fever, as they daily increase the number of deaths. Consequently volunteers for China reserves are becoming more and more scarce.

Famine in China.—The Shanghai correspondent of the *Standard* says that a terrible famine prevails in the Province of Shensi, China. The government reserve granaries are nearly empty. The people in the Sinan Fu prefecture are eating grass, leaves and roots. It is said that there have been cases of cannibalism in the mountains.

London Mission Hospital, Chung-King.—The report for 1899 has been received. The hospital has been rebuilt, with a special ward for Europeans, and accommodates 80 patients. Excepting the surgeon in charge, the whole staff is Chinese and there are 6 native students. The London Missionary Society requires all its Chinese hospitals to be self-supporting.

Obituary.—RICHARD NEALE, of London, November 22, aged 71.—GEORGE MACKAY, of Edinburgh, November 20, aged 80.—REUBEN BOLTON, of Bangor, Ireland, November 20, aged 66.—J. MORTIMER GRANVILLE, of London, November 23, aged 67.—ROGER EDWARDS, of Colwyn Bay, Wales.—November 21, aged 50.—HUO BERGEAT, of Munich.—GEORGE STETTER, of Königsberg, aged 52.—F. ACCONCI, of Genoa.

The Pasteur Institute.—It is reported that since the Pasteur Institute was opened at Kasauli under the direction of Major Semple, 75 patients have sought admission, 62 of whom completed the course. Of these 44 are Europeans and the rest natives. In no case has the treatment ended in failure, though several of the patients had been bitten on the face by dogs and jackals. The institute continues to supply a pressing need.

Passing of the Fiji Islanders.—Dr. Morgan I. Finucane, medical inspector of the colony, is authority for the statement that the black tribe of Fiji Islanders is dying out. This is due not to a small birth-rate, but to an enormous infant mortality, caused by sanitary neglect, filthy houses, and the absence of skilled physicians. It is not expected that much can be done in the way of improving the conditions while the native character remains as it is.—[*Boston Medical and Surgical Journal*.]

Röntgen Rays for Baldness.—The *London Standard* reports that at a meeting of the Vienna Society of Physicians, Dr. Kienböck introduced a man 26 years of age, whose hair had been partially restored by the application of the Röntgen-rays. He had been bald for some years. A round patch on the scalp was subjected 6 times to the influence of the rays for 15 minutes, and during the 2 months the treatment lasted, the man regained his hair on the parts exposed to the action. The parts not yet treated remain as before. During the discussion which followed several members expressed doubts as to whether Dr. Kienböck has really found a remedy for baldness, but he was encouraged to continue his experiments, and invited to report on them to the society at a later date.

Leontiasis Ossea.—Stephenson (*Medical Chronicle*, September, 1900) reports a case of leontiasis ossea occurring in a man of 27. At the age of 13 the patient first noticed a hard, painless swelling on the left side of the lower jaw. This has gradually increased since that time. About 18 months ago a similar swelling appeared on the right side of the lower jaw, and during the past 12 months the bones of the nose have gradually increased in size, the left nostril being almost occluded. Lately there has been some neuralgic pain in the lower jaw. His family history is good. The superior maxillae are slightly enlarged, and there is considerable bulging over the frontal sinus. The cause of leontiasis ossea is not known. It was first described by Virchow and later by Sir James Paget. No treatment appears to be more than palliative. [A B C.]

2.—Tredinnick has collected some interesting sequelae of cranial injuries, and most of them have been under his own observation in private practice. The first series contained 6 cases of moral perversion: 1 a young married woman where the injury was followed by nymphomania, lasting several months; 2 a boy, 3 a girl, both were good children before the injury, but idle, untrustworthy, and bad afterwards; 4 a boy where injury was followed by epilepsy and a propensity for stealing; 5 and 6 were men, and after injury became maniacal and destructive. The psychic area was no doubt involved in all of these cases, as the blow was over the frontal bone. The second series contained 8 cases of traumatic dementia; 8 and 9 committed murder; 10 attempted suicide; 7, 11, and 12 became maniacal; 13 insane; and 14 suffered from mania, but recovered after some of the parietal bone exfoliated and was removed. In a third series he collected 10 cases where diabetes followed, and the location of the injuries was basal, parietal, occipital, at the vertex, and frontal. It was found at several necropsies on these cases that the floor of the fourth ventricle had a ground-glass appearance, such as seen in cases of general paralysis. He divides traumatic diabetes into 2 forms, permanent and transient; the latter usually appears soon after the accident, while the former some time afterwards, even as late as 3 years, but not likely after that time. The fourth series contains 45 cases of epilepsy ranging in age from 6 months to 45 years. The injury in 33 of these cases was occipital, parietal, frontal, and at the mastoid and vertex. The duration of unconsciousness after injury varied from a few minutes to 4, to 7, and even 32 days, while the period between the accident and the development of epilepsy varied from 2 to 17 years. The results of trephining in these cases are interesting. In 24 where the injury was parietal, 1 no result, 1 fits returned, 1 partial recovery, 3 died, and the rest recovered. In 9 cases injured over the same region with no operation 5 died, 1 was cured, and in 3 fits continued. Seven cases of injury to the frontal bone were trephined, 4 recovered, 2 died, and 1, treated with potassium bromid, died; 1 injured over the same region, but not operated upon, died. In the cases injured in the mastoid region 1 improved with operation, and 1 without. The 2 vertex cases were both trephined and recovered, while the 1 occipital case recovered without operation. [W.S.N.]

3.—Ransom reports the case of a man aged 44 years who suffered from attacks of intense darting pain in the left hypochondrium. The patient had come into the hospital at

his own request with the view of being relieved by operation. The attacks of pain recurred with great frequency, often several times a day, and the patient would sometimes have repeated spasms of pain and twitching, each of some seconds' duration, for 12 hours together. The patient insisted on operation, and laminectomy was performed and the cord exposed at the level of the sixth, seventh, and eighth thoracic roots. Nothing abnormal was seen on the cord or its membranes, but the eighth left posterior root was distinctly thicker than the others. Pieces were cut out of the seventh and eighth roots on both sides, those from the eighth root being placed in osmic acid for microscopic examination. The result of the operation was not satisfactory, as, in spite of antiseptic precautions, pus formed in the wound, fever set in, and 6 days later the patient died. At the necropsy the spinal cord showed no definite tracts of sclerosis, but there were diffuse patches of softening, especially near the site of operation. There was no tumor or meningeal thickening, except fresh granulations at the wound, and the remaining nerve-roots looked healthy to the naked eye. On opening the skull, the dura was found to be tough and rather thick, and the pia-arachnoid was thickened and opaque in patches. Microscopic examination of the removed posterior roots showed excess of fibrous tissue and a great reduction in the number of nerve-fibers in the left root, while in the right there was a very slight decrease of the normal fibers. The pathologic process was closely akin to that of *tabes dorsalis*; but instead of degeneration of a large number of posterior roots only a very few were picked out, one especially, the left eighth thoracic, undergoing degeneration of nerve-fibers with formation of fibrous tissue, the growth of which caused the intense pains, reflexly, contractions of the rectus abdominis muscle. [J.M.S.]

4.—Reynolds noticed in his practice an unusual number of patients who were suffering from *peripheral neuritis*. Women were affected more frequently than men, and all the patients were beer or porter drinkers. In many of the cases the skin of the armpits, the nipples, and the genitals was deeply pigmented as in Addison's disease. The neuritis affected either sensory, vasomotor, or motor nerves, or all 3 combined, and was associated with running of the eyes and nose. The author found a considerable amount of arsenic in certain beer used in this district, and Dixon Mann also found arsenic in a different sample of beer. So that it is fair to presume that the arsenic was the cause of the neuritis. [J.M.S.]

5.—In 2 houses taking their water-supply from the same well, the inmates and their friends are known to have been, for at least 12 months, drinking water that was highly contaminated with sewage. No one suffered in consequence until after the arrival of a trooper invalided home from South Africa, convalescent from *enteric fever*. Immediately after his arrival the well became infected with the typhoid bacillus, as proved by the fact that between September 4 (17 days after the arrival of the trooper) and September 17, 12 individuals were laid up with typhoid fever, the only link between these 12 individuals being that each one of them had partaken of water from the polluted well. The water from other wells in the same village has been analyzed and found to contain sewage, but no case of typhoid fever has resulted from the use of the water from these wells. Walker believes the bacilli contaminated the well-water from the patient's urine. It has been shown that in about 25% of cases of typhoid fever the bacillus may be detected in the urine. The author believes that every convalescent soldier should be given a course of urotropin, which will almost certainly clear the bladder of bacilli. [J.M.S.]

6.—Hanford reports the case of a man, aged 47, who was suffering from a nonmalignant stricture of the pylorus, after washing out the stomach for about 1 week with a 1 to 60 boric-acid solution, an *erythematous rash* appeared upon the patient's face and back. Plain water was substituted for the boric-acid solution and the rash disappeared in 2 days. Later, 1 to 200 boric-acid solution was used, and the erythema returned. The use of boric-acid was again stopped and the rash entirely disappeared. After pyloroplasty the stricture was completely relieved and the patient recovered. [J.M.S.]

7.—Long reports the case of a lad, aged 13 years, who received 3 punctured nail wounds on the plantar surface of the big toe. This accident was followed by pain in the limbs

and the patient complained that his legs became stiff so that he fell to the ground. Doses of 10 cc. of *antitetanus serum* were injected hypodermically uninterruptedly every 4 hours for 13 doses. After this the injections were continued 4 hourly for 6 more days by rectum. They were then given 8 hourly for 3 days longer. In all 13 injections were given hypodermically, and 55 per rectum, making a total of 680 cc. of serum used. The patient recovered. [J.M.S.]

8.—Fitzgerald reports 5 cases of *puerperal eclampsia*, the history of which suggests the conclusion that to induce labor, however severe the fits, is a great mistake, the 2 cases so treated terminating fatally; whereas those in which no operative procedure was carried on with a view to remove a cause of the convulsions, recovered perfectly. In both cases in which morphin was used, the fits were checked almost at once by its administration and did not return so long as the patient was under its influence. Another advantage is that morphin is free from the depressing effect upon the heart exerted by chloroform or chloral. The old idea that it exercised a bad effect in cases of renal trouble would appear to have no foundation in fact. [W.K.]

10.—Drummond reports the case of a man, aged 26 years, who was in a state usually described as *lethargy, trance, or stupor*. He had always been more or less melancholic and reserved, and religious to the verge of fanaticism. A neurotic family history was elicited. During his stay in the hospital the patient lay like a nonsentient being, moving neither arms nor legs, and apparently cut off entirely from the outer world. The pulse was about 100; the temperature varied from 97° to 98° F.; and he was conscious. During his treatment a dry cough developed, accompanied by a rise of temperature to 103° F. The left lung was dull on percussion all over and tuberculous disease was suspected. But the condition was relieved by turning the patient on his side, and it is probable that some of the food entered the trachea and blocked the left bronchus. On another occasion a large abscess developed in the tonsil. During the latter attack the urine contained a large quantity of albumin with blood and casts. At the end of 7 months the patient began to improve, and he was convalescing slowly at the time of writing. [J.M.S.]

11.—Hartigan reports the case of a boy, aged 14 years, who had been suffering from *dysentery*. At 1 P.M. he had taken an injection of rather less than 1½ ounces of *lysol* in about a pint of water. At 1 30 P.M. he was found in bed quite unconscious. When first seen he was in a state of complete collapse, and he died in about 5 hours. No postmortem examination was made. [J.M.S.]

12.—Cutfield reports a case of *aortic aneurysm*, which was decidedly improved by injections of a 2% solution of gelatin into the subcutaneous tissue of the abdominal wall. He began with 3 ounces and increased to 4 every second day for 3 weeks; then the injections were every third, then every fourth day until 20 had been given. With the above treatment 5 grains of potassium iodid was given with his meals, but the patient was not confined to bed. [W.S.N.]

12. Six Cases Illustrating the Operative Treatment of Some Forms of Hip-Joint Disease. ERNEST F. NEVE.

1.—Duckworth calls attention to the various **medical conditions that produce mental disturbances**, particularly those types that can be ascribed to auto-intoxication, or the impregnation of the tissues with organic poison, as a result of certain habits such as alcoholism, cocaine, chloral, etc. He mentions particularly in the first class the mental disturbances of Bright's disease, of diabetes, pneumonia, and other fevers, and in addition, puerperal insanity, gout, chorea, rheumatism, etc. In addition, he speaks of acute psychoses occurring in influenza, and mentions general paralysis as probably belonging to the same category. Among the organic poisons he mentions lead (?) and alcohol, and in conclusion he speaks of the mental aberrations due to morphin, chloral, ether, cocaine, etc. He thinks that the average patient nowadays is singularly intolerant of pain. [J.S.]

3.—Trevelyan describes some interesting cases of **diphtheric paralysis**. The first, a girl of 10 years, developed the symptoms 3 weeks after recovering from a doubtful throat infection. There was unsteadiness in walking, loss of the knee-jerks, considerable albuminuria, and ultimately death. The second case, a boy of 8 years, had a typical attack of paralysis of the palate. Immediately after the acute symptoms had subsided there was some disturbance of the ocular muscles, slowing of the pulse, and pains in the legs. There was analgesia, loss of knee-jerks, and loss of power to stand or walk. Respiration became feeble, rales appeared in the lungs, but recovery ensued. The third patient, a boy of 4, had difficulty in walking when he got out of bed. There was albuminuria, loss of the knee-jerks, and complete paralysis of the eye-muscles. The fourth patient, a boy of 5, about 5 weeks after a severe attack of diphtheria, had regurgitation through the nose, internal squint, and dilation of the right pupil. The knee-jerks were absent on the right side. The fifth case, a man of 34, had had a severe attack of diphtheria in June; he subsequently returned to work, but was obliged to give it up on account of unsteadiness and weakness in the limbs. There was Romberg's symptom, ataxia of the lower limbs and loss of knee-jerks. He subsequently improved. The sixth case, a boy of 7, 6 weeks after his attack had unsteadiness in his gait; Romberg's symptom, and loss of knee-jerks. Fluids regurgitated through the nose. Trevelyan gives a very thorough account of the symptomatology of these conditions. Albuminuria is very common in paralytic cases of diphtheria. It was present in all of those whose urine was examined in the present series. Vomiting occurs occasionally in diphtheric paralysis, and is apparently associated with cardiac failure; it is possible that it may be the result of the renal condition. Ataxia is quite common, and was present in 3 of the 6 cases. Diagnosis is usually easy unless the diphtheria has been overlooked on account of its occurrence in some unusual situation. The prognosis is good for complete recovery, unless the patient dies of respiratory failure, or from renal insufficiency. Even when respiratory paralysis seems imminent the patient may recover. The treatment consists essentially of rest combined with frequent and regular stimulation such as hypodermic administration of strychnia or spartein. Electricity may be used to stimulate respiration. [J.S.]

4.—Hosack, in discussing the **diagnosis of plague**, recognizes 6 types: (1) The bubonic; (2) the pneumonic; (3) the septic; (4) the intestinal; (5) the meningial; (6) the carbuncular. The disease commences suddenly, and there are the following characteristic symptoms: The dorsum of the tongue is coated, but the edges, the tip, and often the median raphe remain clean or dry. The pulse-rate is invariably out of proportion to the general condition of the patient; the pulse itself is quick, feeble, compressible, and even running. Muscular incoordination is common; there is blurring of the speech; the expression is anxious, and there is considerable mental confusion and stupidity, deepening into stupor and coma, often with muttering delirium. Hosack, however, mentions a number of cases in which the intelligence was unimpaired until a few moments before death. Speaking of the different types, the *bubonic* is usually readily recognized; the inguinal glands are usually enlarged, but any others in the body may be affected. In 193 cases, 149 were bubonic. The *pneumonic* type may be either primary or secondary to some other form. Respiration in this form is not abnormal or hurried, the characteristic signs being those of consolidation at the apices. Microorganisms

may be obtained from the sputum. The *septic* type can be diagnosed only by elimination. The *intestinal* type can be distinguished from cholera by the high fever and the blood in the evacuations. The *cerebral* type is characterized by the symptoms of meningitis, none of the characteristic symptoms of which are found at the autopsy. The *carbuncular* type is exceedingly rare; the carbuncles have a marginal, rather than a deep induration, and do not cause pronounced excavations. Plague may sometimes be confounded with puerperal fever, septicemia, pyemia, smallpox, and other infectious diseases. [J.S.]

5.—Griffiths reports a case of **Landry's paralysis**. There was much general malaise, then severe pains in the legs, complete paralysis of the lower extremities gradually involving the abdomen and chest, impairment of sensation, and finally death 3 days after the onset of paralysis. As influenza was epidemic, Griffiths regards it as possible that this was the cause. [J.S.]

6.—Brownlie is convinced that **Ichthyol** is the most valuable drug in the treatment of eczema, acne, and other **superficial inflammatory conditions**. In acute cases he employs application varying from 2% to 5% in strength; in the chronic cases, from 5% to 10%, and in acne vulgaris, from 10% to 25%. At the same time he administers the drug internally. It is not valuable for the relief of itching. [J.S.]

7.—Keith reports the case of an infant which, because of obstructed urination, underwent circumcision when 1 week old. The child did not breathe well under chloroform and lost more blood than usual. The physician when called to the child during the night after the operation, found it to all appearances dead though its heart was still beating. He at once resorted to **artificial respiration**, which was continued for 14½ hours with slight interruptions, and the child ultimately recovered. One of the astonishing facts about the case was that the amount of brandy which the child required was for its age enormous. A smaller amount than 20 drops every hour was tried and the same quantity at longer intervals, but the result under both conditions was the same—it at once seemed to lose ground. The brandy was never at any time thrown off by the lungs; at least it was never noticeable in the breath, so that it is probable that the child used it all up in the struggle for its life. It is also wonderful that this small child, only a week old, was able to stand the manipulation, which did not seem to have injured it in any way. It was simply marvellous to see how quickly the marks resulting from the prolonged movements disappeared from its chest, abdomen and arms. This long cessation from natural breathing was probably caused by the combination of the chloroform, the shock, the hemorrhage and the disordered stomach, but what part each played in the pathologic condition it is difficult to determine. [W.K.]

8.—Williamson has employed **plasmon** in 55 cases of various diseases such as acute gastritis, chronic gastro-intestinal catarrh, anemia, various infectious conditions, tuberculous diarrhea, carcinoma and cardiac disease. It always acted well, even when the patient had been suffering from nausea and vomiting, it improves nutrition rapidly and therefore is of great benefit in profound anemias. His personal experience has been that on hunting trips it enables him to stand much more fatigue than any other article of diet. It is best administered in milk, barley broths, etc. [J.S.]

9.—Richards suggests the following method for the **estimation of iron in animal organs**. Fifty or 100 grams of the moist organ are weighed in a platinum dish, then dried and charred, and the mass remaining moistened with strong nitric acid. It is then incinerated gently, treated a second time with the acid, again incinerated, and treated with pure hydrochloric acid for 5 minutes. It is then warmed and transferred to a beaker, and after the addition of a few drops of strong nitric acid, carefully boiled. The solution is then diluted, filtered, and the filtrate brought up to 50 or 100 ccm.; 20 ccm. is taken and transferred to a Nessler glass and treated with 1 ccm. of potassium ferrocyanide, when the mixture is made up to 50 ccm.; if the color is too intense a smaller quantity should be taken. This color is compared with one given by a standard iron solution, the most convenient being 0.1 gram of pure iron, dissolved in hydrochloric and nitric acid and diluted with distilled water to one liter. At the same time small portions of the viscera should be dried to a constant weight in order to

estimate the amount of moisture in it and the percentage of iron calculated on the dried viscera. [J.S.]

10.—The following case is reported as one of probable **perforating gastric ulcer**, the diagnosis being based on the presence of a large quantity of free gas within the peritoneal cavity, though perforation was not found. A woman of 22 who had never suffered from pain after taking food was suddenly seized with violent abdominal pain which continued during the night. She vomited once, but the following morning as the pain had abated she took a little breakfast. The pain immediately recurred with great severity, and she again vomited. On admission to the hospital she was suffering severely. The pulse was 146, respirations 52, temperature 103. There was constant retching but not vomiting. The abdomen was greatly distended, tympanitic, and tender everywhere, especially in the region of the ensiform. The abdomen was opened between the ensiform and the umbilicus and gas escaped freely. The anterior surface of the stomach was covered by a thick layer of lymph. At one place this coating was as thick as the palm of the hand. On partially removing it 3 elevated dusky spots were seen. No evidence of perforation was found though because of firm adhesions the under surface of the stomach not examined. The abdominal cavity was flushed with boric-acid solution and closed without drainage. No vomiting followed the operation. Nutrient enemata were given for the first 3 days. Convalescence was complicated by stitch-abscess necessitating opening part of the wound. Since her recovery the patient is strong and well. [M.B.T.]

11.—A woman, 50 years old, was trodden on by a cow while milking. She felt something give way inside and after suffering for some time from acute abdominal symptoms was admitted to the hospital almost moribund. She was deeply jaundiced and all the symptoms of peritonitis were present. Celiotomy was performed, and a large quantity of bile, pus and some fecal matter was evacuated. The abdomen was flushed with an antiseptic solution and a drainage tube was inserted. The patient was so weak and the parts were so matted together that further intervention was not considered justifiable at the time. The patient made a perfect recovery, however, a further operation not being necessary. The case is reported as one of traumatic **rupture of the gallbladder**, though the precise seat of rupture was not determined. [M.B.T.]

12.—Neve believes that the results obtained by a late incision or drainage in the treatment of **hip-joint disease** compare very unfavorably with those obtained by **early exploration**, arthrectomy or sequestrectomy. Exploratory operation reveals the exact nature of the disease, the condition of the synovial membranes and bones, and the presence of sequestra. It is more successful if performed early, before pus has escaped from the joint-cavity and burrowed in the planes of the fascia. In progressive hip-joint disease, specially where tension and pain are on the increase, early operation is strongly indicated. When sepsis is secured and the operative treatment is judicious and adequate, the immediate results may be ideal. The conception and permanence of the cure depend upon the maintenance of rest for a sufficiently prolonged period until the tissues of the joint area are sufficiently consolidated to bear the weight and strain of the body without injury. An anterior incision is considered preferable. Six cases of early operation for hip-joint disease are reported in which the results were very satisfactory. [M.B.T.]

New York Medical Journal.

1. The Operation for Hypospadias, with the Demonstration of Three Cases Successfully Treated by the Forward Dislocation of the Urethra. CARL BECK.
2. The Present Status of the Treatment of Prostatic Hypertrophy in the United States. RAMON GUITÉRAS.
3. Notes on the Hospital Scarlet Fever Service in New York City from 1893 to 1899, Inclusive. WILLIAM L. SOMERSET.
4. A Plea for General Anesthesia in the Treatment of Mammary Abscess. FRANK H. FIELD.
5. Mastoid Abscess. RUFFIN A. WRIGHT.
6. What is Normal Menstruation? GEORGE J. ENGELMANN.

1.—Beck in his study of hypospadias cases, collected over 100 in which marriage proved fruitless, and he believes it to be more common than usually credited. In the French army it occurs once in every 300 recruits. The neglect of these cases in childhood he thinks is criminal. Beck's method for making a normal urethra is a simple procedure when the **hypospadias** is not severe, and his results have been surprisingly favorable. The preponderance of elastic tissue in the urethra allows it to be stretched with very little difficulty after it has been dissected free from its bed and after a channel has been made through the glans it is simply pulled into position and stitched with iodoform silk sutures, then the wound is closed below. After these cases heal there is not the slightest bowing during erection. In one severe case after a phagedenic ulcer where there had been considerable loss of tissue this method failed, but he was able to restore the urethra by inverting the skin and then covering it with a flap from the scrotum. When operating on infants great care must be used in the dissection of the urethra. His youngest case was only 5 months. [W.S.N.]

2.—Guitéras, in reviewing the **present state of treatment of hypertrophied prostates in the United States**, divides the course into the conservative and the radical methods. The former consists in preventing the growth of the gland by proper medication, and care with the bladder in regard to drawing off the retained urine after each urination. When the case needs frequent use of the catheter, the best method is for the patient to carry a number of them with him wrapped in a sterile towel, and to sterilize them before using again. The radical method consists of operation; although many have been devised, they have all been discarded, except Bottini's and prostatectomy, both of which have strong advocates; he, however, believes the condition of the case should decide the operation, and 3 things should be considered: (1) The age of the patient; (2) the size and shape of the prostate; (3) the condition of the kidneys and bladder. If the condition of the patient is poor, Bottini's method is the best, although many contend it is not good surgery. Of the prostatectomies Alexander's, Syme's, and Fuller's are usually performed, but he prefers a method devised by himself, which he calls the rectovesical method. A suprapubic cystotomy is performed, then 2 fingers of the left hand are inserted into the rectum, while the point of a pair of scissors is pressed into the prostate through the opening in the bladder; when the point is through the gland, and can be felt through the rectum, the gland is then cut, the finger of the right hand is inserted into the cut, and the substance shelled out. Bleeding is then controlled by hot water. After this an opening is made in the perineum for drainage, through which a gauze drain is introduced, while a catheter is placed in the suprapubic opening. [W.S.N.]

3.—Somerset has found that in the very earliest cases of **scarlet fever** the eruption is frequently present on the anterior axillary fold. Projectile vomiting is a very common early symptom. In favorable cases the maximum temperature is about 103°. The erythema following injection of diphtheria antitoxin frequently simulates the rash of scarlet fever. The patient should be kept in bed and on fluid or semifluid diet for 3 weeks in order that treatment may produce the best results. [J.M.S.]

4.—Field, in a plea for **general anesthesia in the treatment of mammary abscess**, states that when a local anesthetic is used one is not apt to open it as thoroughly as he would otherwise, and the abscess is likely to extend more deeply and widely than might be foretold by examination before operating. [W.S.N.]

5.—Wright supports the views of Harrigan in regard to early operation in cases of **mastoid abscess** (see PHILADELPHIA MEDICAL JOURNAL, Vol. VI, p. 940), and by this means to lessen the number of complications. [W.S.N.]

6.—Engelmann has studied the **normal menstrual function** in 5,000 girls between the ages of 15 and 26 years. In 31% the function recurred every 28 days; in 45% it was retarded, and in 24% it occurred oftener than once in 28 days. The irregularities increase as the duties of the patient become more stringent or as mental or physical exertion become more intense. The average duration of the flow was 4.6 days. Suffering averages 67%; from 11 to 18% suffer severely, and, as a rule, there is an increase of 10% with increased mental strain. The period is characterized by an intensification of all vital energies, followed by a depression

that appears with the flow. It is a period of heightened susceptibility, and is so sensitive as to record any variation from the normal quickly. The functional condition of the girl in good health, under modern conditions of life, is by no means the ideal one, and, in fact, the functional health of the American girl, the coming mother of American men, is far from what it should be by right of inheritance and surroundings. [J.M.S.]

Medical Record.

December 8, 1900. [Vol. 58, No. 23.]

1. Tuberculosis of the Eye; Its Differential Diagnosis, Pathology, and Treatment. CHARLES STEDMAN BULL.
2. The Treatment of Tumors by Electrolysis. WILLIAM B. NEFTTEL.
3. Infant Feeding. LOUIS FISCHER.
4. A Mistake in Therapeutics. EDWARD P. BUFFET.

1.—Bull regards **tuberculosis of the eye** as rare and its **diagnosis** as difficult, as in many cases the bacilli and the giant cell are the only determining factors. Tuberculous ulcers of the conjunctiva and lids usually occur through the infection of some abrasion, and when they do the lymphatic glands around the ear are also involved. When the process is primary the **prognosis** is favorable. The sclera and cornea are not often invaded and show great resistance. The uveal tract is usually secondary to pulmonary or other process. The iris and ciliary body are sometimes invaded by the disease in the primary form; if so, it generally results in phthisis bulbi. When the retina or optic nerve is involved it is usually an extension from the meninges. No cases of primary tuberculosis of the orbit have ever been reported. [W.S.N.]

2.—Nettel believes that **electrolysis in the treatment of tumors** is a safer and more reliable method than the use of the knife. He derives this opinion from over 30 years of study and experiment. This method was used before the days of antiseptics, and its application was never followed by such complications as hospital gangrene, pyemia, etc., the reason for this being that ozone and hydrogen peroxid are both produced by the interchange of radicals around the anode and cathode when an electric current is passed through the tissue; while this is going on at the same time there is a destruction of tissue, which is followed by necrosis. This destruction of tissue can be modified by the direction of the current and the number of diaphragms, and the different densities of the tissue between the poles. Besides this there is a diffusion of the swelling which favors absorption. He does not believe that the electrolytic action is increased by the injection of metallic salt (as zinc); when this action alone is not beneficial it cannot be improved by the cataphoresis of metallic salts. Around the anodal needle a dark layer is formed due to mummified tissue, which then undergoes a necrobiosis and a soft eschar follows. Considerable care must be employed in introducing the needle, but he has introduced it into the liver, spleen, and joints for a few seconds to even a minute without unpleasant effects. This, however, could not be done with the anode, as in this case the necrotic destruction is produced en masse; although he has introduced a carefully insulated needle into an aneurysm, in malignant growths this necrosis en masse is desired. Electrolysis has yielded good results in treating enlarged prostates and its action here is the same as in treating uterine fibromyomata. He introduces a well-insulated cathode into the gland, per rectum, and the anode is placed over the abdominal wall, then a weak constant current is allowed to pass through for a few minutes. [W.S.N.]

3.—Fischer objects to the use of **boiled, sterilized, or pasteurized milk**. Raw milk should be used, and the milk should be obtained in such a manner that there is no opportunity for its infection. Heating the milk causes changes in the albuminate of iron, in the phosphorous compounds, and perhaps in the fluorin compounds which make the iron and fluorin compounds unabsorbable and the phosphorus unassimilable. Each infant should be fed by its own special law. Rules cannot be made for all children. If a food is chosen for an infant it is necessary to see that the child appears satisfied, that there is no vomiting and no colic, that the bowels move without artificial aid and the stool is yellowish white and soft. The infant should sleep for

from 4 to 8 hours at one time during the night, the weight should be taken regularly, and there should be an increase of from 6 to 8 ounces per week; if the weight does not increase the food should be changed and every factor in the child's life should be investigated. Fischer has found that the children fed on laboratory milk have been backward in movement for a long time; it seems to produce constipation, and later gastric and intestinal atony, poor appetite, delayed dentition, and rickets. The children are usually anemic. When milk disagrees Fischer finds almond milk useful. This he prepares by scalding or blanching the almonds, then beating up an ounce of blanched almonds in an ounce of water, rubbing the mixture and expressing it through cheese cloth; one ounce of almonds thus yielding one ounce of almond milk. Dextrinization of foods is useful in case the digestion is subnormal. It should never be used except during illness, however, as if there is no demand upon the glands for their ferments they will become atrophied. The hydrochloric acid is practically always reduced in young children during gastrointestinal disturbance, hence hydrochloric acid may rationally be given. The two drugs which he finds most useful are nux vomica and malt. [D.L.E.]

Medical News.

December 8, 1900. [Vol. lxxvii, No. 23.]

1. An Improved Technic in Amputation of Large Rectal Prolapse. GEORGE RYERSON FOWLER.
2. A Modification of the Mosquito Theory. CHARLES R. GRANDY.
3. Heat-Stroke as a Postoperative Complication. C. L. GIBSON.
4. Chloralamid. S. V. CLEVINGER.
5. State Sanatoria for Consumptives in Michigan. HERBERT MAXON KING.
6. A Study of Drainage. A. M. POND.

1.—Fowler **amputated a large rectal prolapse** under spinal cocaineization and has to some extent **improved the technic** of the operation. The mass protruded about 5 inches and was of about 5 years' duration. The patient was placed in a combined lithotomy and Trendelenburg position. The advantage of this position is that the small bowel is not so liable to be injured. The prolapse is then caught, where the skin and mucous membrane join, by a pair of fenestrated forceps, and about a $\frac{1}{2}$ inch in front an incision is made and extended around and only through the mucous membrane; the proximal end is dissected back for about a $\frac{1}{2}$ inch; 2 clamps are placed on either side just where the outer cylinder returns to become the inner one; after the cylinders have been recognized the incision is deepened to a $\frac{1}{2}$ inch and a suture of catgut is placed so it will include both cylinders, then they are cut and another suture is placed, afterwards cut again, and so on around the whole bowel. Care must be taken so as not to cut in excess of the suture, and during the last part of the operation a steady stream of borosalicylic solution is played over the field of operation. [W.S.N.]

2.—Grandy believes that the **mosquito theory** explains the prevalence of **malaria** in those months when mosquitos abound, and the reason that malaria does not occur in those parts of the world where only the *Culex* is found, as in northern Michigan. He objects to it because it apparently claims that malaria can only be propagated by the direct transmission from one human being to another through the mosquito, because in districts which have been depopulated as a result of the prevalence of the disease, the disease reappears as soon as human beings return to them. It seems certain that malaria is not transmitted by the water supply, and Grandy therefore suggests that possibly there are other intermediate hosts besides man, or it may be that the parasites are capable of living in damp places where the mosquitos feed, and can in this condition infect the mosquitos even if not human beings. It is true that the plasmodium has never been cultivated artificially, but this is true of all other parasitic protozoa. [J.S.]

3.—Gibson believes if it is possible to postpone **severe operations in hot weather** it should be done, as the complication of **heatstroke** in postoperative cases is to be dreaded; and if it does not give rise to any severe trouble it is apt to produce considerable worry on the part of the oper-

ator. In cases that demand operation the patient must be kept in a cool room and a constant circulation of air such as is produced by an electric fan is advisable. [W.S.N.]

4.—Clevenger recommends **chloralamid** in various conditions in which a hypnotic is required. It seems to sustain the system rather than depress it, is particularly valuable in melancholia, toxemic neuroses, psychoses, and seems to be particularly indicated in delirium tremens. The usual dose is from 15 to 60 grains one-half hour before bedtime, but as much as 120 grains may be given in the course of a day. [J.S.]

5.—King advocates the establishment of **State sanatoriums** for consumptives, because "the open-air treatment systematically carried out, and supplemented by such general medical treatment as the individual case may require, is our most effective weapon against tuberculosis." Of course the rich have long been able to avail themselves of this method, but the poor have hitherto been obliged to remain in their own houses, or the city hospitals, with disastrous results. As a result of the experiments of various physicians in Germany and the United States, King recommends that no sanatoria of greater capacity than 200 patients be constructed, and he believes the initial expense of such an institution need not exceed \$150,000, and the cost of maintenance would be about \$8.00 per week per patient. Altogether he estimates that not more than 500 patients at one time would require care in the State of Michigan. [J.S.]

6.—Pond believing that the **serum that exudes from wounds** has distinct **antiseptic properties**, believes that drainage is rarely of advantage after operations. He believes it should be restricted to cases in which all other means have failed to render the wound antiseptic or noninfectious. [J.S.]

Boston Medical and Surgical Journal.

1. The Treatment of Placenta Prævia by Cesarean Section, With Report of Successful Case. FRANCIS D. DONOGHUE.
2. The Duties of the Medical Examiner in Massachusetts. JULIAN A. MEAD.
3. A Case of Alexia, Mind Blindness, Etc., with Autopsy. EDWIN E. JACK.
4. Note on the X-rays as a Curative Agent in Certain Diseases of the Skin. FRANCIS H. WILLIAMS.

1.—Donoghue regards the condition known as **placenta prævia** as today the most **fatal condition** with which the obstetrician has to deal, showing a death-rate, fetal and maternal, higher than almost any other obstetrical condition. He considers 4 methods of treatment: (1) Induction of premature labor; (2) rupture of membranes followed by natural delivery or delivery by forceps; (3) manual dilation of os with delivery by version; (4) cesarean section. The first, induction of premature labor, is based solely on the desire for the safety of the mother without regard to the child's life and should not be justified before the seventh month. The second method is useful in cases of lateral or marginal placenta, where good pains are present and os dilated or dilating; but it is not recommended where immediate delivery is indicated, or in cases of complete previa. The third method, the treatment of placenta prævia by manual dilation followed by version, is the method almost universally followed today by English and American obstetricians, and has shown in the hands of experts a steadily decreasing maternal mortality; but it can hardly be called an ideal treatment, since while it has reduced the maternal mortality to probably the lowest point attainable (about 12%), it has done so at the expense of the fetus. Cesarean section, Donoghue considers quite as favorable for the mother and much more so for the child and as indicated in preference to any other method: (1) cases of complete previa; (2) cases of previa in primiparas when signs of fetal or maternal exhaustion are evident; (3) when the condition of rigid os is present; (4) where there is a history of a previous operative delivery; (5) in transverse positions and in cases of prolapsed cord, if the cord is not easily returnable. That cesarean section is the easiest of all celiotomies all who have performed it admit, and it is generally considered an extremely safe operation

for both mother and child. Reynolds reports 19 cases from his own practice and 74 by Leopold and Evarkes without a maternal or fetal death. Donoghue gives a full description of a case of successful cesarean section under conditions in which any other mode of delivery must have been fatal to at least one of the lives involved; and he thinks this example offers hopes of success to others when confronted by the same grave emergency. [W.K.]

3.—Jack reports the case of a man, aged 63 years, who was suffering from **alexia and mind-blindness**, both partial and of the cortical variety, and **amnesic color-blindness**. The lesion was thought to be on the left side at the region of the angular gyrus and in the occipital lobe, probably aparing the cuneus and the calcarine fissure. At autopsy it was found that the inferior aspect of the left temporal lobe presented an area of softening that occupied its middle third; posterior to this the dura was adherent to the brain over an area 4 by 5 cm. Upon section through the area of adhesion, a spherical mass presented that involved the third temporal convolution in its most posterior part and the gyrus fusiformis. In front of the mass and extending somewhat deeper into the substance of the left occipital lobe, there was a region of softening apparent only on the under surface of the brain. Microscopically the tumor proved to be a **glioma**. [J.M.S.]

4.—Williams' experience with the **x-rays as a curative agent in lupus** has demonstrated: 1. That excellent results can be obtained by exposing the diseased portion of the skin near a Crooke's tube which is giving off x rays, and that the treatment causes no pain and that it is not necessary to repeat it so frequently as to produce an inflammatory reaction. 2. That it is essential that the treatment should only be undertaken by one who has learned how to manage an x-ray apparatus and has provided himself with special appliances for carrying out the method. [J.M.S.]

10. A Critical Summary of the Literature on the Serum Diagnosis of Tuberculosis. DAVID L. EDSALL.

1.—Harrington has seen 18 cases in which the application of dilute solution of carbolic acid to the extremities for a number of hours produced gangrene. The result is not due to compression, but is caused by the carbolic acid itself. The gangrenous process may be so slight that only the skin is destroyed, or it may cause complete disorganization of the affected part. The action of carbolic acid is insidious and its use as a moist dressing should be entirely abandoned, as a large part of the benefit conferred by it can be derived from a moist dressing obtained by the use of boiled water on clean compresses. The article is provided with a number of excellent illustrations, one of them of a microscopic section, and a long bibliography is appended. [D.R.]

2.—A committee was appointed by the American Surgical Association to report on the medicolegal relations of the x-ray, since skiagraphs are destined to figure largely in suits for damages after accidents and in cases of malpractice. A circular letter was sent to every member of the Association by J. William White, the Chairman of the Committee, and from the answers received the following conclusions were drawn: 1. The routine employment of the x-ray in cases of fracture is not at present of sufficient definite advantage to justify the teaching that it should be used in every case. If the surgeon is in doubt as to his diagnosis, he should make use of this, as of every other available means, to add to his knowledge of the case; but even then he should not forget the grave possibilities of misinterpretation. There is evidence that in competent hands plates may be made that will fail to reveal the presence of existing fractures, or that will appear to show a fracture that does not exist. 2. In the region of the base of the skull, the spine, the pelvis, and the hips, the x-ray results have not as yet been thoroughly satisfactory, although good skiagraphs have been made of lesions in the last three localities. On account of the rarity of such skiagraphs of these parts, special caution should be observed when they are affected, in basing upon x-ray testimony any important diagnosis or line of treatment. 3. As to questions of deformity, skiagraphs alone, without expert surgical interpretation, are generally useless and frequently misleading. The appearance of deformity may be produced in any normal bone, and existing deformity may be grossly exaggerated. 4. It is not possible to distinguish after recent fractures between cases in which perfectly satisfactory callus has formed and cases which will go on to nonunion. Neither can fibrous union be distinguished from union by callus in which lime salts have not yet been deposited. There is abundant evidence to show that the use of the x-ray in these cases should be regarded as merely the adjunct to other surgical methods, and that its testimony is especially fallible. 5. The evidence as to x-ray burns seems to show that in the majority of cases they are easily and certainly preventable. The essential cause is still a matter of dispute. It seems not unlikely when the strange susceptibilities due to idiosyncrasy are remembered that in a small number of cases it may make a given individual especially liable to this form of injury. 6. In the recognition of foreign bodies the skiagraph is of the very greatest value; in their localization it has occasionally failed. The mistakes recorded in the former case should easily have been avoided; in the latter they are becoming less and less frequent, and by the employ-

ment of accurate mathematical methods can probably in time be eliminated. In the meanwhile, however, the surgeon who bases an important operation on the localization of a foreign body buried in the tissues should remember the possibility of error that still exists. 7. It has not seemed worth while to attempt a review of the situation from a strictly legal standpoint. It would vary in different states and with different judges to interpret the law. The evidence shows, however, that in many places and under many different circumstances the skiagraph will undoubtedly be a factor in medicolegal cases. 8. The technicalities of its production, the manipulation of the apparatus, etc., are already in the hands of specialists, and with that subject also it has not seemed worth while to deal. But it is earnestly recommended that the surgeon should so familiarize himself with the appearance of skiagraphs, with their distortions, with the relative values of their shadows and outlines, as to be himself the judge of their teachings, and not to depend upon the interpretation of others who may lack the wide experience with surgical injury and disease necessary for the correct reading of these pictures. [D.R.]

3.—In a woman of 27 years, who presented symptoms of acute ascending paralysis, the urine had a claret color, was acid, contained a trace of albumin and indican, but no sugar, and had a specific gravity of 1.020. A chemico examination showed the presence of hematoporphyrin. The patient had received trional and sulfonal. The latter has been known to produce hematoporphyrinuria, but there was a history of the passage of dark-colored urine before either was administered; and, moreover, the hematoporphyrinuria continued for 14 days after the administration of only 1 gram of each of the two drugs. [D.R.]

4.—The Brown-Sequard paralysis in Wood's patient was due to a stab-wound in the neck. Immediately after the injury the left arm and left leg were paralyzed. Two months later the man could use his left arm slightly, and could walk, but with an uncertain manner. A year later there was a fine tremor of the left leg and, to a lesser degree, of the left arm. There was diminution of power in the left arm, and atrophy of both left arm and left leg. On the paralyzed side the tactile sensibility was increased, while on the nonparalyzed (the right) side tactile sensibility was greatly diminished. There was hyperesthesia to painful impressions in the paralyzed limb; analgesia in the other. Muscular sense was lessened in the paralyzed, unaltered in the nonparalyzed, members. Temperature-sense was increased in the paralyzed and lost in the nonparalyzed limb. There was then on the side of the lesion a paralysis of voluntary movement, of muscular sense, and probably a vasomotor paralysis, the paralyzed leg being much warmer than the nonparalyzed. There was also hyperesthesia of the trunk and limbs, increase of reflexes, and ankle-clonus, while in the nonparalyzed side there was anesthesia. [D.R.]

5.—In a woman of 58 years who had had several attacks of dacryocystitis of the right side, Veasey excised the lacrimal gland and sac. On the eighth day after the operation the patient began to have pain in the eye, and by the following day a severe membranous conjunctivitis of both eyes had developed. The cornea of the right eye, which was not anesthetic, was slightly abraded near the center and considerably roughened. Bacteriologic examination showed only the diplococcus of Fraenkel. The disease increased and the cornea became marked with fine lines, giving the appearance of a lattice-work. The cornea also became partially anesthetic; the membrane disappeared entirely from the left eye, but continued to form on the right. Thyroid extract was administered; and whether as a coincidence or as a result, the eye began to improve. The lattice-like appearance continued for some time; but of the corneal capacity, only a slight haziness in the lower, inner quadrant remained. The author believes that the corneal condition was probably the result of injury to some portion of the trigeminus. He does not think that the mechanical theory advanced in explanation of so-called trophic keratitis can satisfactorily explain this case, since anesthesia did not present itself until some time after the corneal disease had been established. Moreover, protection of the cornea, instead of securing improvement, made the condition worse. He is inclined to the belief that the affection was produced by some disturbance of the trophic nerves of the cornea. Whether there is a special set of

trophic nerves or whether it is a part of the function of the trigeminus to exercise trophic influence over the cornea remains undetermined. [D.R.]

6.—Oliver has made a careful study of the **eye-symptoms in posterior spinal sclerosis**, a disease which he divides into an optic and a spinal type. The former occurs in from 10 to 15% of all cases, and is characterized at first by fair or normal vision. Later, visual paresthesias and contractions of the fields manifest themselves. There may be spastic movements of the extraocular muscles and slight swelling of the optic disc. Gradually, if the disease is not arrested, atrophic processes develop in the optic nerve, which may eventuate into complete blindness. In the spinal type there may be, despite objective changes in the disc, normal vision, with irregular and slightly indented color fields. The pupils are myotic and in advanced stages the iris remains absolutely fixed to the strongest light stimulus. [D.R.]

7.—A small amount of albumin and a few casts are not uncommon in the urine of any cases of **diabetes mellitus**, but during or just preceding **diabetic coma casts** may appear suddenly in extraordinary numbers. The sediment obtained by the centrifuge or by sedimentation may consist almost entirely of light-colored, finely granular casts. When recovery takes place the casts may entirely disappear. This presence of casts in diabetic coma, to which Kulz and Aldehoff first called attention, Herrick has observed in three cases. The author has also seen several instances of **low specific gravity of diabetic urine**. This may be because of the development of interstitial nephritis. In such cases the sugar may be gradually reduced to a minimum or disappear entirely. He has seen sugar present with a specific gravity of 1.004 in a case of diabetes. A number of instances of specific gravity below 1.010 with the presence of sugar in the urine have been reported. The lowest recorded is a specific gravity of 1.002. [D.R.]

8.—Ophüls has made a careful study of the **pneumonic complications of tuberculosis**. The material bringing about these complications is usually derived from cavities, and the question arises, What bacteria are the responsible agents? The author examined 26 cavities in 13 cases, and found *Streptococcus pyogenes* in 1, the *pseudodiphtheria bacillus* in 5, the *pneumococcus* in 6, the *pneumococcus* and *pseudodiphtheria bacillus* in 4, the *staphylococcus* and *streptococcus* in 2, the *pneumococcus* and *staphylococcus* in 1. The infectious material is carried to other parts of the lung by aspiration or by gravitation. In those cases in which the cavities are not surrounded by a continuous membrane of granulation and scar tissue, the pathogenic organisms may enter adjoining healthy portions of the lung directly through the cavities, without traveling first through the bronchial tubes. Among 56 phthisical patients examined with regard to pneumonic complications, the latter were found in 25. Some were produced by the tubercle bacillus acting alone, and in this form the histologic lesions differed from the bronchopneumonia due to mixed infection. Different types of this true tuberculous pneumonia are recognizable. One may be termed the acute, of which there were 9; one, the chronic, characterized by the presence of tuberculous granulation tissue; besides which there is a still more advanced form, characterized by calcification. The acuteness of the process seems to depend to a certain extent upon the number of tubercle present in the diseased spot. The condition of the patient also appears to exercise an influence. The area of tuberculous pneumonia may become the seat of a secondary infection, by way of the bronchial tubes. Such an infection favors the disintegration of the caseous material and the formation of cavities, but it is not essential to this end. The outcome of tuberculous pneumonias is usually unfavorable. There is a rapid caseation and disintegration of pulmonary tissue. In the more chronic cases there may be a tendency to fibrous tissue formation. In other forms of pneumonia there is a mixed infection from the beginning. Among 16 of such cases there were 9 cases of bronchopneumonia without caseation, 4 with apparently very rapid and extensive caseation, and 4 with calcification. The bacteria found, together with the tubercle bacillus, were the following: *Pneumococcus*, 10 cases; *streptococcus*, 1; *pseudodiphtheria bacillus*, 1; *pseudodiphtheria bacillus* and *streptococcus*, 1; *pneumococcus* and *streptococcus*, 1; cocci of an unknown nature, 1. It is very likely that the acute pneumonic process set up by a mixed infection can heal. Clinically

the recovery may be, and often is complete; but the presence of tubercle bacilli in the lesions makes it very probable that anatomically the process will not heal completely, but with a remaining more or less extensive simple, tuberculous lesion. Ordinary lobular and lobar pneumonias may occur in the course of phthisis, but they do not seem to be frequent, and the author found only two cases of bronchopneumonia and one of lobar pneumonia in which no tubercle bacilli could be discovered in the exudate. It has been asserted that such simple pneumonic complications could be secondarily infected with tubercle bacilli, but the author does not think that anatomic proof has been brought of such an assertion. [We are quite sure that such secondary infection is possible, and only recently we saw a case in which a typical lobar pneumonia, coming on after anesthesia, failed to resolve and passed into tuberculous caseation.] The pneumonic complications are frequently accompanied by generalized infections through the bacteria that are associated with the tubercle bacilli in causing them. Regarding the **diagnosis** of mixed infection, the author does not think that an examination of the sputum by Kitasato's method of repeated washings of the sputum in sterilized water is of much value, since various pathogenic bacteria may be found in cavities without their necessarily causing mixed infection. [D.R.]

9.—In a woman, 30 years of age, a tumor the size of an orange was found opposite the third rib on the right side of the chest anteriorly, the skin being freely movable over it. At operation the tumor was found to be a **multilocular cyst** with a thick, brownish fluid, containing small particles of gritty matter. The patient failed slowly and died of exhaustion. At the postmortem examination a cavity 6 by 8 cm. in size, was found, bounded by the pleura on the inner surface of the right lung and by the pericardium. The wall was more or less covered by fatty, granular detritus, in which some light-colored hairs were seen. A number of polypoid excrescences sprang from the cyst wall. The tumor was firmly united to the pericardium, pleura, and diaphragm. Microscopically it presented the feature of **dermoid cyst** with squamous epithelium and sebaceous glands; there was also some cartilage. Together with the author's case, there are now on record 37 examples of **dermoid cyst of the mediastinum**. After discussing the embryology and etiology, the following classification is suggested: 1. True dermoids, containing only ectodermal structures. 2. Teratomata, or dermoids with the addition of structures from the endoderm and mesoderm. 3. True dermoids, or teratomata with the addition of tumor formation. [D.R.]

10.—The difficulties attending the extension of the **Widal serum reaction to tuberculosis** have been the facts that the tubercle bacilli in ordinary culture-media are not homogeneously distributed and that they are not motile. It has been shown, however, that in some cultures the bacilli exhibit an active movement, whether corpuscular or voluntary, is not known, and that by frequent agitation of liquid cultures a fairly homogeneous distribution of the bacilli through the medium can be secured. An attenuated bacillus grown in glycerin-peptone bouillon should be used, and the culture should be from 8 to 10 days old. Only the upper portion of the culture should be taken. The blood from the patient is drawn into small tubes, and the serum obtained by allowing the clot to retract spontaneously or by centrifugation. The reaction does not occur with normal serum in a dilution of 1:5, and in a tuberculous subject it rarely occurs in dilutions greater than 1:20. Serum and culture should be mixed in small tubes in the proportion of 1:5, 1:10, and 1:20. The tubes should be kept inclined at an angle of 45° and examined after 2, 10, and 24 hours. If reaction occurs the mixture becomes clarified and deposits small flakes along the lower edge of the tube, and microscopically the bacilli are found to have formed clumps and to be no longer motile. Of 186 persons, 128 gave a positive reaction. Of these, 96 were known to be tuberculous or proved to be so. Ten of the negative cases were also definitely known to have tuberculosis. These were all advanced cases. Twenty apparently healthy persons were examined and 6 gave the reaction; but there was no opportunity for determining whether these 6 subsequently showed tuberculosis or not. Experiments demonstrated that poorly marked reactions or none are seen in those who are suffering from a very severe or virulent tuberculous infection, and perhaps in those who are exces-

sively susceptible. Agglutination takes place more readily when the bacilli used in the test are homologous with those causing the infection. Edsall feels hopeful that the method may be of value. At any rate, the importance of the subject suggests further investigation. [D.R.]

Wiener klinische Wochenschrift.

August 30, 1900. [13. Jahrg., No. 35.]

1. The Pathology of Icterus. BROWIEZ.
2. Experiences with C. L. Schleich's Marble-dust Soap. ERNST FUCHSIG.

1.—The author's conclusions regarding the **production of jaundice** are: 1. The basis of jaundice is an increased function of normal liver-cells, which, excited by different stimuli, produce more bile or bile-pigment. 2. Only a normal liver-cell which can take up and elaborate an excess of nutriment and thus can produce an increased quantity of bile, can eliminate this excess of bile into the intercellular bile-passages, whence part of the bile passes into the blood; in part directly through the walls of the blood-capillaries; 3. The mechanic factor has only an indirect influence, in that it disturbs the intravenous circulation in the blood-capillaries. 4. The bile reaches the general circulation through the **blood-capillaries of the hepatic veins** and only to a slight extent through the lymphatics of the larger bile-channels. 5. All forms of icterus can be explained in the way designated, viz.: on an increased functional activity of the liver-cells, which means an overproduction of bile or bile-pigment. [D.R.]

2.—With the gradual loss of confidence in the value of chemical disinfectants for the **sterilization of the hands** there has been increased importance placed upon the value of mechanical disinfection. Schleich has gone so far as to discard chemical disinfectants entirely, and uses a soap containing marble-dust as a mechanical disinfectant. Fuchsig has tested this method of sterilizing the hands in Professor Albert's clinic at Vienna for 6 months and has carried out a series of bacteriologic experiments to determine the value of the method. After sterilizing the hands according to this method the fingers were placed on sterile agar plates. Out of 33 different tests the plates remained sterile in only 4 cases. In spite of these unfavorable results from a bacteriologic standpoint, Fuchsig finds that practically the results are very good, and he considers this method of pure mechanical disinfection an advance in the methods for sterilizing the hands. Among other advantages he mentions that there is never eczema nor irritation of the skin following the use of the marble-dust soap. [M.B.T.]

1. Assimilation Disturbances Among Infants with Stomach and Intestinal Diseases. MEINHARD PFAUNDLER.
2. Honthlin, an Intestinal Astringent, and its Therapeutic Application in the Diseases of Children. JOSEF REICHEL.

1.—Pfaundler subjects the theories of Czerny's school at Breslau to criticism, basing his strictures on his own researches and those of others. Czerny and his pupils maintain that the principal disturbance in the **chronic intestinal diseases of children** consists in an **acid intoxication**, the evidence of which is found in an increase in the elimination of **ammonia** in the urine, while the normal share of NH_3 in the newborn is 7.8—96% of the total urinary nitrogen. Keller found it in infants with gastroenteritis from 20 to 50%. Keller believed that the fats in the food were especially productive of acids. The ammonia, according to older views, is formed in the system for the purpose of combining with and neutralizing abnormal acids. Pfaundler examined the urine of 40 children, 30 being under 6 months of age. Some were healthy as regards the alimentary tract (magendarmgesund), others had various gastrointestinal affections (magendarmkrank). He found very little difference in the quantity of ammonia eliminated. The coefficient seemed to depend more on the general health than on the state of the bowels. Gastrointestinal diseases, it seems, influence the coefficient only indirectly, i. e., to the extent to which they impair the func-

tions of respiration, circulation, and metabolism. No marked difference was found in the **toleration of fats** between healthy children and those ill of gastroenteritis—the coefficient of NH_3 increased nearly equally in both with equal increase in the quantity of fat administered. The NH_3 coefficient, in Pfaundler's opinion, is largely, though not exclusively, under the sway of the food, particularly the fats. The fat of human milk does not seem to increase the NH_3 to the same extent as that of cow's milk. Thus, there is in every artificially fed infant a certain degree of hyperacidity, but this cannot be called an acid intoxication, since the circulating acids, as long as they are neutralized by NH_3 , do not do any serious damage. Pfaundler also believes that disturbances in the liver are of influence on the proportional distribution of the urinary nitrogen. In examining the oxidative properties of liver-tissue from the cadavers of infants with healthy and from those with diseased livers, he found that diseased liver had far less power to oxidize salicylaldehyd into salicylic acid than healthy liver. Comparative studies of the urine and subsequently of the oxidizing property of the liver showed that whenever the NH_3 was increased above the mean, the production of salicylic acid from aldehyd was reduced below the mean. These facts indicate that the **oxidative energy of the liver** has an important influence on the **nitrogen-distribution** in the urine of infants; when the energy is diminished, as in cases of anatomic changes in the liver, the NH_3 in the urine is increased at the expense of the urea. The existence of an acid intoxication in infants with gastroenteritis can only be proved by the discovery of diminished alkalinity and CO_2 contents of the blood, a proof not hitherto brought forward. [D.R.]

2.—**Honthlin**—named after the discoverer's town—is a tasteless, nonhygroscopic powder; chemically it is a tannin preparation in which the albumin tannate has been keratinized. It is insoluble in water, partly soluble in alcohol. In doses of 0.25—0.38 (4-5 grains) for infants, and 0.3—0.5 (5-7½ grains) for older children, four times a day; it is a safe and reliable intestinal astringent. [D.R.]

September 13, 1900. [13. Jahrg., No. 37.]

1. The Significance of Acoustic Speech-Centers as Inhibition (?) Organ of Speech Mechanism. A. PICK.
2. The Present Position of Radiotherapy. E. SCHIFF and L. FREUND.
3. Therapeutic Application of Frictional Electricity in Medical Practice. BRITUNG.

1.—A lesion in the left auditory speech-center is accompanied by a peculiar disturbance of speech—a condition termed **paraphasia**. The patients present a condition suggestive of a **lack of inhibition** and react in an exaggerated degree, and usually in a constant manner, to all forms of stimuli, but particularly to that through the auditory channels. The speech appears as if it were produced reflexly, involuntarily, or automatically. The words roll from the mouth in a constant, disordered stream of incoherent sentences. In other cases there is a typical **logorrhoea**, apparently excited by all kinds of external stimuli, but particularly by those of an auditory nature. This logorrhoea is quickly exhausted, but renewed with successive stimuli. Pick believes with Collins and others that these phenomena are due to the failure of action of the **normally acting inhibitory mechanism**, which has its seat in the **temporal lobe** and coincides, perhaps only in part, however, with the acoustic speech-center. Against the theory that logorrhoea and paraphasia are due to irritation of Broca's region may be cited the fact that such phenomena are never observed in exclusive lesions of this region—not even in cases such as tumors which preeminently give rise to irritative symptoms. The **paraphasia** must be looked upon as a **temporal-lobe symptom**, and it does not occur when Broca's region is also involved in the morbid process. Against the irritative theory is also the fact that in exclusive lesions of the temporal lobe there was never any evidence justifying the assumption that this lesion exerted any irritative action on Broca's convolutions. On the contrary, the speech phenomenon is best marked when the distant effects are reduced to a minimum, and when the functions of the temporal lobe are alone disturbed. The lesion in the tem-

poral lobe is not one of irritation, as in such cases hallucinations of hearing and perhaps of smell and taste occur; paraphasia, sometimes appearing in a modified form as echolalia, is produced only when the lesion no longer causes irritation, but paralysis of the temporal lobe. In favor of the inhibition theory is, in addition to what has already been mentioned, the fact that the phenomenon of paraphasia occurs especially in softening, in which effects at a distance are minimal; while in the case of apoplectic foci the symptom is not apt to occur, on account of the marked distance effects of such a lesion; and also the curious fact that in injuries of the skull involving this region the paraphasia may occur suddenly after the lifting of the compression bone fragments. The paraphasic logorrhea sometimes observed in petit mal may be explained on the ground that there is a local disturbance of the temporal lobe, as the result of which there is a reflex logorrhea; in other words, that an automatic function takes the place of the voluntary. Echolalia in its more marked forms is also a speech reflex, developing under conditions similar to those giving rise to paraphasic logorrhea; that is, when the function of the left auditory speech center or its immediate neighborhood is eliminated or greatly disturbed. Whether the inhibitory function coincides with the real function of the acoustic speech center, or whether there is only a spatial and partial coincidence, cannot be determined at present. [D.R.]

2.—The chief indications of radiotherapy are skin affections, particularly those produced by parasites and those in which removal of hair is a prerequisite for cure. The special indications are: (a) Lupus vulgaris and mycoses of the skin; (b) hypertrichosis, sycosis, favus, folliculitis, furunculosis, acne, etc.; (c) lupus erythematosus. Sycosis and favus require only a few weeks; hypertrichosis, a year and a half. The changes produced by the rays are ascribable to an influence on the vessels of the skin. Freund has studied physiologic action of the silent discharges and of the invisible rays. He comes to the conclusions that: 1. The direct discharges may bring about falling of the hair. 2. The direct discharges are capable of inhibiting the growth of or killing bacterial cultures. 3. This effect is also produced if thin layers of wood, paper, aluminum, stanniol, or human skin, intervene. 4. It also manifests itself on bacteria suspended in liquid media. 5. The physiologic action of the negative discharges is more intense than that of the positive; but it is, on the other hand, more limited in extent. 6. By a special apparatus it was found that the silent discharges are a modification of the visible discharges, differing from the latter somewhat in intensity, but also having less undesirable after-effects, as for instance pain. Their scope of use is greater than that of the direct spark, and their mode of action qualitatively the same. 7. Röntgen-rays, according to these observations, have no physiologic properties. 8. Becquerel and phosphorescence rays have likewise no physiologic action. 9. The pathologic changes produced in the skin by the direct sparks consist in hemorrhages, inflammations, and vacuolization. Regarding the treatment of lupus, the authors believe that for small areas extirpation with subsequent transplantation of skin is the ideal method. Röntgen therapy should be applied only to large, deeply ulcerating processes, and to cases in which objection is made to operation. Röntgen therapy is preferable to Finsen's method on account of its simplicity. The authors assert their claim to priority in the use of the Röntgen-ray in dermatology. [D.R.]

3.—Breitung is a believer in the value of high tension currents in insomnia, hysteroepilepsy, tinnitus aurium, and has had constructed a special apparatus for their application. In cases of partial deafness the method may momentarily produce an increase of deafness, but this passes off. It should, however, be remembered and the patient informed of it in advance. [D.R.]

Berliner klinische Wochenschrift.

September 3, 1900. [37. Jahrg., No. 36.]

1. Injuries to the Eyes by Calcium. H. SCHMIDT-RIMPLER.
2. Treatment of Leprosy. W. DÖNITZ.
3. Concerning Angina Pectoris. MAX SALOMON.

4. Malignant Epithelial Tumors of the Upper Nasal Cavity. J. HERTZFELD.

5. Bacteria in the Intestinal Wall. G. POSER AND J. COHN.

1.—Schmidt-Rimpler states that there have been 56 injuries of the eye from calcium or some of its combinations during the past 10 years in the Göttingen Clinic. These injuries are the most common burns or injuries of the eye by corrosive substances. Most of the patients were masons or laborers who handled calcium or some of its derivatives. In 10 cases both eyes were injured. In 20 of the patients blindness resulted. Hence the importance of immediate careful treatment can be readily seen. The eye is usually firmly contracted. By some means it should be opened so that every particle of the calcium can be carefully removed from the cornea and conjunctival sac. Removal is best accomplished by the use of oil. A bit of cotton can be saturated and used to wipe out the particles. It is especially important to evert the upper lids, as particles are prone to become embedded in them. To relieve the pain holocain is recommended and the eye should be thoroughly flushed out with oil. If no oil can be found, water may be used, for as a rule, the calcium has been dissolved and water causes no rise of temperature. The prevention of these accidents is highly important, and the use of protective spectacles by workers in calcium is recommended. [M.B.T.]

2.—Dönitz discusses the value of chaulmoogra oil in the treatment of leprosy. The oil is obtained from the seeds of the *Gynocardia odorata*, and has for many years been used internally. When given subcutaneously it produces a local and general reaction. The latter consists in a rise in temperature, persisting for several days; the former, in a reddening of the effected portions, and particularly a pericyclic congestion of both eyes. The injections in the author's cases were repeated only after the ocular phenomenon had subsided. After a few injections the infiltration in one of the cases diminished, and in about 4 months had entirely disappeared. In addition to the chaulmoogra oil the patient had received sulfur baths. As it was doubtful which had been the efficient agent, when a second case presented itself only the chaulmoogra oil in the form of hypodermic injections was employed. The injections were followed by a local and general reaction, and a gradual reduction in the size of the nodules. The most striking effects were seen in the eyes. There had been marked pannus, and one eye was practically blind. At the end of the treatment the pupil was so far clear that light could enter. The injections are given at intervals of from 10 to 14 days, and in such small doses that the temperature rises only about 0.5°C. From .1 to .2 grams (1½ to 3 grains) are sufficient. There is some analogy between the local and general reactions produced by chaulmoogra oil and those produced by tuberculin, but the former, of course, has no specific influence, and probably more nearly resembles cantharidin in its action than tuberculin. It is likely that it also has an influence upon other affections, particularly those of syphilitic and perhaps those of tuberculous origin. [D.R.]

3.—Five cases of angina pectoris presenting no special features are briefly described. Arteriosclerosis of the coronary arteries plays the most important part in the disease, but there are other causes. In the treatment the iodids enjoy the greatest reputation, but in Salomon's opinion they are of value only in those cases that are dependent upon coronary sclerosis. Whether in a given case there is such a sclerosis is often not determinable. The palpable vessels frequently show no change, and the heart presents nothing noteworthy. The history may, under these circumstances, be of value, particularly when it reveals the existence of syphilis or alcoholism. There is an angina pectoris of neurasthenic origin which differs from the arteriosclerotic form in no way except in the prognosis. The treatment in general consists in the use of the iodids and in the dietetic and hygienic regimen. [D.R.]

5.—Posner and Lewin in 1894 and 1895 showed that after occlusion of the rectum intestinal bacteria invaded the blood and organs in from 24 to 48 hours. These results were attacked by Markus, who claimed that in the occlusion of the rectum some injury was produced which allowed the entrance of the bacteria by way of the lymph paths. As an answer to this objection, Posner and Cohn have made a series of experiments on rabbits, in which they closed the anus

with collodion and found that after a certain length of time *Bacterium coli* could be found in various organs. In one animal they injected the *Micrococcus prodigeus* into the rectum and then closed the anus with collodion, cotton, cambric, and plaster of paris. Two days later the animal was killed, and the prodigeus was found in the urine, kidney, peritoneum, liver, spleen, and blood of the heart, as well as in the intestinal contents. Regarding the portal of entry into the organs, the authors believe that it is by way of the blood, since in previous experiments the kidney was sterile if the renal artery was ligated. There is, then, no doubt that under certain conditions the **intestinal wall is penetrable by bacteria**, but it is probable that the perfectly normal bowel opposes their passage. The conditions favoring the entrance of bacteria into the general system are either mechanic or the action of pathogenic bacteria. In their own experiments the disturbance did not bring about any gross lesion in the continuity of the bowel. Hyperemia and hemorrhages were present, but nowhere were there any tears in the mucous membrane; but of course the vitality of the bowel suffered in the experiment. The experimental conditions are somewhat analogous to those obtaining in fecal impaction and in blood stasis; as, for instance, in the death agony and in incarcerated hernia. The experiments, although of a severity but rarely duplicated in man, suggest that certain infections of the urinary tract not produced by instrumentation may be due to intestinal bacteria. [D.R.]

Münchener medicinische Wochenschrift.

September 11, 1900. [47. Jahrg., No. 37.]

1. The Prevention of Puerperal Fever. M. HOFMEIER.
2. A New Method for the Observation of Injuries to the Living Cells and Organisms. MAX NEISSER and FRIEDRICH WECHSBERG.
3. Method of Showing the Capsule of Bacteria in Solid Culture Media. ICHILIO BONI.
4. The Clinical Diagnosis of Typhus Abdominalis. ALFRED BERLINER and MARTIN COHN.
5. Cavernous Angioma of the Cerebrum. THEODOR STRUPPLER.
6. A Journey in Switzerland during an Epileptic Trance-State, and the Transitory Disturbance of Consciousness before the Judge in a Criminal Court. GEORG BURGL.
7. New Instruction to Bavarian Midwives Concerning the Prevention of Pye-suppurat in the Newborn. SIOMUND NEUDURGER.

1.—Hofmeier reviews the statistics of 5,000 obstetric cases, there being no deaths from **puerperal sepsis** in the last 1,000 cases. He also reviews much literature on the advantages and disadvantages of aseptic and antiseptic measures in diagnosing obstetric cases as well as in operative obstetrics, and finds little which tends to oppose his opinion or change his conviction that it is in the interest of the patient, and also practicable, in obstetric operations, especially in intrauterine operations, thoroughly to cleanse and disinfect, not only the external genitalia, but also the vagina, before examination or operation. The practical difficulties can be overcome if desired and the results warrant the most careful carrying out of these fundamental principles. [W.K.]

2.—Living cells, particularly leukocytes, have the **power of reducing methylene-blue** and decolorizing its solutions. If leukocytes are suspended in physiologic salt-solution in a narrow test-tube, and a drop of dilute methylene-blue solution is added, the mixture overlaid with liquid paraffin, and the tube placed in a thermostat, complete decolorization of the methylene-blue occurs in a short time. If the leukocytes are killed by leukocidin, by heating, or by quinin, the solution remains blue. The sediments present the same difference in color. The authors suggest this method for determining whether cells are living. It is applicable to spermatozoa, as well as to immobile cells like those of the kidney or pancreas. It may also be employed for bacteria to test the influence of bactericidal substances. Various enzymes and ferments tested gave no reduction. The method can also be used for determining roughly the bactericidal content of milk. The absolute sterility it does not determine. No dye gives as clear results as methylene-blue. [D.R.]

3.—The **formation of capsules by bacteria** can be demonstrated when the bacteria comes from bouillon and other fluid culture-mediums, but hitherto it has not been found in bacteria grown on solid mediums. Boni found the reason that the capsules were visible in the former case to be that the dye stained the bouillon or other liquid medium. Cultures from solid mediums are usually mixed with distilled water, and as the latter does not fix the dye, there is no contrast produced between the pale capsule and the surrounding substance. It occurred to the author to use a fluid that would stain, and thus by contrast show the capsule. He uses a mixture of the white of 1 egg, 50 grams of glycerin, and 2 drops of formalin. This is shaken and then filtered. A drop of the filtrate is placed on a coverglass or slide and a trace of bacterial culture stirred in it. It is then heated until the formation of steam no longer occurs. The staining is done with undiluted Ziehl's solution. In this way he was able to demonstrate the capsule in the diplococcus when grown on agar and also capsules in certain other bacteria. Of particular importance was the discovery of a capsule about *Bacillus coli* and the absence of such a capsule in the typhoid bacillus. [D.R.]

4.—A careful clinical study of 45 cases of **typhoid fever**, from which the authors conclude that the Widal test is of great value. In addition to the microscopic method, they employ a microscopic reaction obtained in a shallow watch glass. After 30 minutes at room temperature a precipitate settles in the form of a star-shaped figure. Prognostically the Widal test has no value. The existence of complications, such as pneumonia, do not interfere with the Widal reaction. In 3 cases renal hemorrhage occurred. They recovered, as do most cases complicated with affections of the kidney. In some of the cases they found small ulcers in the mouth, which they consider was due to the typhoid bacillus. [D.R.]

5.—In a patient, a woman of 48, who without previous symptoms of any moment developed signs of Jacksonian epilepsy, beginning in the right arm and leg, the author diagnosed a **brain tumor**. There was no optic neuritis. At the autopsy a tumor the size of a small hazelnut was found at the upper end of the sulcus of Rolando and situated in the anterior central convolution. There was also hypoplasia of both occipital lobes, and beginning granular atrophy of the kidneys. Microscopically the tumor proved to be **cavernous angioma**. The bloodvessels in the tissue surrounding the tumor were degenerated. Struppler believes that the growth belongs to the **erectile tumors** and that the sudden development of grave cerebral symptoms, despite the smallness of the tumor, was probably due to a hyperemic swelling of the growth. [D.R.]

6.—The patient whose interesting history Burgl details was a cabinetmaker, married, of neurotic ancestry. One day he suddenly disappeared and turned up in Switzerland at the home of his parents, in his working clothes and with his tools. He was brought back and remembered dimly his escapade. Before he left he had been much disturbed by the illness of his wife, and yet, although he was homesick for his parents, nothing had been further from his mind than to desert his family at that time, but an uncontrollable impulse overpowered him. No one had ever seen him in a typical epileptic attack, but in infancy he had had spasms, and later in life he had on several occasions at night shown a twitching of the lips, had bitten his tongue, and had risen in the morning with a headache. On two occasions he had been guilty of self-exposure. He was also subject to somnambulism, had frequently done absurd acts, was at times melancholy, and harbored ideas of suicide. Sometimes he was almost maniacally excited, and then would have complete or partial amnesia afterwards. Not rarely he had vertiginous seizures, transitory losses of consciousness, and causeless attacks of profuse perspiration. Several times since his marriage he had wet the bed at night. When a boy he had received a severe box on the ear, which was followed by partial deafness. In consequence of the second attempt at exhibitionism, he was brought before the court, and his case was entrusted to the author for expert judgment. Burgl looked upon the case as one of epileptic **dämmerzustand**, that is, an **epileptic trance state**. It has been held by many that there is always amnesia for acts committed in such a trance, but this statement does not hold good. Usually the patient is not unconscious, but the consciousness is pecu-

liarly modified, and he remembers to a certain extent what happened in the altered state. The epileptic attacks in which unconsciousness occurs are the typical major epilepsy, petit mal, and epileptic vertigo. In the trance condition consciousness is usually preserved for at least part of the seizure. Such cases are generally associated with attacks of vertigo. The fact that an individual remembers an act does not disprove the epileptic nature of the state in question, nor is complete amnesia a sure sign that, during the attack, consciousness was totally lost. There may be a transitory recollection of the attack and of what happened in it, which may subsequently vanish. When is a transitory disturbance of consciousness to be considered epileptic in nature? After all other diseases producing epileptiform attacks are excluded, **the existence of epileptic psychosis may be predicated**, first, if typical convulsive seizures have been demonstrated; secondly, if several well-marked states of trance have been observed; thirdly, if there have been transitory attacks of vertigo, with pallor of the face, or a feeling of sinking and falling and a necessity for seizing the nearest object, and fleeting attacks of unconsciousness (petit mal). If anyone of these is present, the epileptic nature of a disturbance of consciousness is not in doubt, but it is permissible to assume the epileptic nature of a condition also when each disturbance of consciousness is preceded by the same so-called epileptoid phenomena. The latter are night-terrors, intermittent bed-wetting, causeless profuse perspiration, certain neuralgic pains, unreasonable attacks of fear, paroxysms of moroseness, irritability, or a destructive tendency, uncontrollable temper, brief periods of profound depression, absurd hypochondriac notions, etc. All these are nothing more than motor, secretory, sensory, or psychic equivalents. These signs have an additional value when there is an hereditary taint and when the individual has sustained some injury to the head. It may be very difficult to convince the judge or jury of the epileptic nature of an act. When it can be demonstrated that there is complete amnesia, acquittal usually follows, as the absence of all recollection has been considered as proof of the absence of consciousness during the performance of the particular act; but if it is shown that an individual may remember, a judge not familiar with psychiatric subjects will usually condemn the accused. However, it will generally be possible to convince the court that while the patient may remember more or less what he did during the performance of the crime, his mentality was disturbed in such a way that free exercise of the will was impossible. Simulation is common in nonepileptic individuals, as well as in epileptics who knowingly commit a crime, and they often feign amnesia of all acts that might incriminate them. The statement of complete forgetfulness should always arouse suspicion. Three other cases are cited of criminal acts committed during attacks of transitory disturbances of consciousness of epileptic origin. The first patient obtained goods under false pretenses. He had a neurotic family history. At the age of 11 he had received a stab wound in the brain in the frontal region. He was subject to frequent epileptic attacks. The second patient was guilty of exhibitionism. His father and father's brother were paranoiacs. He had never had epileptic seizures, but often had headache and vertigo; was forgetful, intensely irritable, could not tolerate alcohol, and at times was confused and did absurd things. The third, a mail carrier who at the age of 7 had suffered a fracture of the skull requiring trephining, had suddenly destroyed a bundle of letters. He had not had epilepsy, but had attacks during which he became deathly pale, stopped suddenly in his work or conversation, staggered a little, and held on for a moment until consciousness returned. All 3 patients were acquitted. [D.R.]

7.—Neuburger says that the frequency of **ophthalmia neonatorum** and its dangers should not be underestimated; that in Nürnberg from 150 to 165 cases are treated yearly, and that in 4 years, 5 children became blind in both eyes and 17 in one eye, from this disease, often the result of lack of care on the part of nurses or midwives. As a means of prevention he thinks such persons should be taught that immediately after the care of the navel cord, all sebaceous matter, blood, etc., should be removed from the eyelids. When the child is bathed, the eyes should be bathed, not in the same water, but in other clean water. Then when the child is laid on the table to be clothed, open each eye a little

with 2 fingers and bring a very small glass tube near the cornea and let fall tiny drops of a 2% solution of silver nitrate. Further treatment of the eyes is usually unnecessary, and if a slight redness or swelling of the lids and mucous secretion continue, the drops must not be repeated in the next 24 or 36 hours. The statistics of Stockholm show a decrease of ophthalmia from 1.2% to .24% of the newborn; and Neuburger thinks we ought not to be satisfied until ophthalmia neonatorum has decreased in all civilized countries and blindness from this cause is no longer known. [W.K.]

September 18, 1900. [47. Jahrg., No. 38.]

1. The Appearance and Diagnosis of Gout. A. STRÜMPPELL.
2. Gallbladder Inflammation and Consequent Stomach and Intestine Disturbances. W. FLEINER.
3. Acute Leukemia. A. DENNIG.
4. The Indications and Technic in Operation for Myoma. A. MARTIN.
5. Phlegmonous Gangrene. G. MUSCATELLO.
6. The Treatment of Abscesses of Joints with Glass Speculum Drainage and Pure Carbolic Acid, with a Report of 70 Cases. A. M. PHELPHS.

1.—Strümpell believes that **gout** is much more common, particularly in Bavaria, than is usually supposed. It is always important to obtain an accurate history of every case that might possibly be one of gout. The characteristic features of joint-gout are: 1. The wellknown **podagra** attack, but the disease may also appear first in the ankle, the knee, or elsewhere. 2. If several attacks occur, the **lower extremities** will be found more frequently involved than the upper; in both cases the distal portions are the preferential seat. 3. The disease is usually **monoarticular**, or at least **oligoarticular**. 4. An important feature is the **multiplicity of attacks**, the patients being seized much more frequently than in acute articular rheumatism. 5. The **duration** of each attack is generally shorter than in rheumatism. 6. Regarding the symptoms of the attack itself, they are wellknown. Strümpell believes, however, that the digestive disturbances emphasized by Sydenham are not common nor important. The elimination of uric acid is not of much diagnostic value. There are also forms of **larval gout**, the recognition of which is difficult. The most important of these are the following: A **chronic arthritis**, often mistaken for rheumatoid arthritis. The presence of tophi and the history of previous acute attacks aid in the diagnosis. 2. Different forms of "**algias**," such as tarsalgia, achillodynia, atypical sciatica, and pains in the soles of the feet, are not rarely gouty. 3. The **gouty kidney**. In these cases the acute attack of gout may have preceded the kidney lesion by years. The possibility of **lead poisoning** should also be investigated. If there is a tendency to the formation of uric-acid concretions, the diagnosis is easier. 4. The gouty manifestations in the **heart and arteries** are not always easily determined. Gouty persons often show marked arteriosclerosis at a comparatively early period of life. As alcoholism frequently coexists, it is hard to know which has the larger share. At times the gout and the cardiovascular changes are coordinate phenomena due to the same cause. 5. **Anomalies in metabolism** have a certain relation to gout, particularly **diabetes and obesity**. Obesity, gout, and diabetes, or any two of these, may occur in the same individual. 6. Larval gout may appear in the form of **chronic skin and mucous membrane affections**. Regarding the etiology of gout, the causes are external and endogenous. The external causes are particularly alcohol and lead; the endogenous cause is heredity. [D.R.]

2.—Two forms of **gallstone colic** may be distinguished: The simple, spasmodic or labor-pain-like colics, and the colicky pains which are produced by inflammation of the gallbladder and the stretching of the gallbladder wall by exudates. The simple gallstone colic is usually produced by mechanic irritation of the gallbladder wall, causing it to contract spasmodically in an effort to expel the stones. To illustrate the mechanic origin of the gallstone colic, Fleiner cites the case of a woman who was examined in the clinic by a number of students. The insensitive gallbladder was freely manipulated, and the crepitation of the stones could be felt. Suddenly the gallbladder became tense and hard, and the

woman had pain, so that she had to be taken home immediately. Some days later she returned in great joy and brought with her 120 gallstones which had been passed on the day after the clinical examination. Nevertheless, Fleiner does not consider such manipulation is without danger. The other form which is also called gallstone colic is usually connected with inflammatory processes in the gallbladder and its environment, with **cholecystitis** and **pericholecystitis**; that is, localized peritonitis. These inflammations, as a rule, do not begin so suddenly as the simple gallstone colic. Calculous cholecystitis and cholangitis are usually of an infectious nature. Cholecystitis calculosa is at times unattended by severe pains, and the diagnosis is then very difficult. Jaundice may be absent. Fever, usually of an intermittent character, is generally present. Passage of the stones occurs in about half the cases. The mechanism of the evacuation is that the tension of the exudate forces out the stone. The exudate may also flow past the stone into the intestine and be evacuated. In rare instances it is absorbed. Necrotic and ulcerative processes are often induced in the wall of the gallbladder by the overdistention and favor the perforation by gallstones. **Jaundice** is by no means a constant symptom of gallstones; it is usually absent when the disease process is confined to the gallbladder and cystic duct, but it may be present, and is then connected with functional disturbances in the liver cells. **Tumor** is one of the most important diagnostic signs. It may take on the form of the dilated and distended gallbladder. At other times the exudate may cause adhesion of the gallbladder and neighboring organs, and produce complicated masses that are often mistaken for malignant growths. In cases of acute pericholecystitis in which the symptoms set in violently, perforation by gallstones into the abdominal cavity should be suspected. Immediate operation is often, but not always necessary, since some of the cases heal spontaneously. Stomach and intestines are frequently involved in diseases of the gallbladder. There are gastric and intestinal colic, vomiting and diarrhea, hematemesis and melena, symptoms of ulcers and actual ulcers, tumors, stenosis of the pylorus, duodenum and colon, hypersecretion, and gastric tetany. The pains originating in the gallbladder are often referred to the stomach and considered gastralgic. Examination of the gastric juice may be necessary to determine to what extent the stomach is involved. If there is hyperchlorhydria, an ulcer should be suspected. The absence of hydrochloric acid is against ulcer, and suggests that the pains are due to gallstones, without, however, proving this. Ulcers in the stomach and duodenum, and even in the large intestine, are not rare in gallstone disease. The ulceration, however, usually occurs from without inward. It is probable that some of the **gastric and intestinal hemorrhages in gallstone disease** are due to such ulceration. Several interesting cases are cited in illustration. In one of these, a woman of 56, who had had a history of pains in the stomach, was suddenly seized with fainting and had tar-colored stools. A year later she again began to have pains in the stomach region, with heartburn, pain in the back, and frequent vomiting of sour fluid. Fear of pain caused her to eat very sparingly and she emaciated rapidly. On examination a tumor the size of a fist was found in the pyloric region. It was considered malignant. Examination of the stomach contents showed the presence of food even in the fasting stomach, and considerable hydrochloric acid. At operation the tumor was found to be composed of an enormous amount of **scar tissue** passing from the gallbladder to the pylorus. The gallbladder no longer contained stones. Another case was that of a man of 46, who complained of pains in the stomach and back after eating, and of pyrosis. He had had biliary colic without jaundice and without the passage of stones. A large amount of free hydrochloric acid was present, even in the fasting stomach. There was pain in the region of the gallbladder, at the point where the mammary line and the costal border intersect. Fleiner suspected an ulcer either in the stomach or just beyond the pylorus. Examination revealed an indistinct resistance in the region of the gallbladder, passing toward the stomach and the hepatic flexure of the colon. A diagnosis of adhesion of the pylorus and colon to the gallbladder, with coexisting gastric ulcer, was made, and the condition attributed to gallstones and pericholecystitis. The patient refused operation. In another case that came to autopsy,

the pylorus, duodenum, and hepatic flexure of the colon, were all drawn in a radiating manner toward the point where the gallbladder should have been, and fastened there by strong adhesions. The colon communicated, through a perforation into the remains of the gallbladder, with the duodenum and the stomach. After careful discussion the gallbladder was found to be atrophied and to consist of 2 little sacs, one containing stones. Stones were also found in a sac at the junction of the duodenum and pylorus. A case is also related in which an inflamed and dilated gallbladder produced functional motor insufficiency of the stomach. Regarding the **diagnosis** of these interesting conditions involving the gallbladder region, the author points out the importance of a careful history, and of attention to the subjective sensations of the patient. The pains usually radiate toward the back and the right hypochondrium. The attacks of colic are frequently preceded by a sensation of drawing and chilliness along the back. A valuable diagnostic sign is a **tender point at the intersection of the right mammary line with the costal border**. In all complicated or obscure diseases of the abdominal cavity it is well to think of the gallbladder and the appendix. In the **treatment** of gallstone diseases the question of operation is an important one, but general rules can hardly be given. When the stones are forced out by a cholecystitic attack operation is unnecessary; when, however, after a colic convalescence does not occur, stones are not discharged, and fever persists, and there is a tumor, or when the attacks occur so frequently as to incapacitate the individual, an operation is indicated. Internal treatment is of value, and consists in diet, alkaline mineral waters, lavage, and oil infusions into the bowel. [D.R.]

3.—In connection with a case of **acute leukomia** in a woman of 22, the author details the principal symptoms of the disease. The distinction between acute and chronic leukemia, which some base upon the duration, the author, with Fraenkel, would base upon the character of the onset, which in the acute form is always sudden, with symptoms that while present in chronic leukemia, develop only late in that form. The first symptoms are weakness and prostration, headache, pains in the limbs, sometimes difficulty in swallowing, hemorrhages into the skin and from the mucous membranes, and sometimes hemorrhages into the brain. An important early symptom is **stomatitis**, which was present in the author's case. Pain in the left side, probably connected with the spleen is common. The spleen need not be enlarged. This is also true of the lymph-glands. The liver is usually enlarged. The pulse, as a rule, is accelerated, and is faster than would be expected from the temperature. The bones are at times sensitive to pressure. The blood picture is characteristic and showed a **marked increase of mononuclear leukocytes**. Nucleated red corpuscles are rare. The lesion is probably in the bone marrow, rather than in the lymph-glands. Walz designates this form of leukemia as lymphocyte-leukemia, while Löwit, on account of the increase of one type of lymphocytic elements, gives it the name of homoicyte leukemia. In Dennig's case the lymph-glands were not much enlarged. There were ulcers in the intestine, resembling typhoid ulcers, but there was no Widal reaction. The author draws the conclusion that it is important in every case of stomatitis without known cause, especially when associated with hemorrhagic diathesis, to make a blood-examination. [D.R.]

4.—In Martin's opinion, **operation for myoma** is indicated when it interferes with the patient's activity and usefulness, shows evidence of undermining the general health, and causes severe pain or discomfort which increases in spite of therapeutic measures. The vaginal operation is preferable so long as the uterus is readily accessible through the vagina and the tumor can be removed with little or no injury to the pelvic floor. It is suitable for an isolated myoma; for one involving only a small part of the uterus so that there will be a reconstruction of the uterus after enucleation; or in case of a pedunculated, subserous tumor. If the growth is very large; if it involves the greater part of the uterus; or there are extensive adhesions, these are indications for an abdominal operation, either supravaginal amputation or total extirpation. To control hemorrhage he uses the angiotribe with the addition of ligatures. The mortality in his last 2 years' experience has been, for vaginal enucleation, 2%; for vaginal total extirpation, 3.5%; abdominal enucleation, 4%; and abdominal total extirpation, 8%. [W.K.]

5.—Muscattello and Gangitano in this their third article on that form of **gangrene** which is accompanied by the formation of gas, treat the subject from a clinical standpoint. As a result of their work they arrive at the following conclusions: That the gangrene which is accompanied by the production of gas can be caused by several forms of microorganisms. *Bacillus aerogenes capsulatus* is one of the most important bacteria, but it should not be considered as the specific, exciting cause. It is simply a gas-producing bacteria which locates itself and grows wherever there is a saprophytic decomposition taking place and where there is disturbances in the vitality of the deeper tissues. *Bacillus coli communis* may cause the development of the gas-producing gangrene, but is usually accompanied by other microorganisms. Clinically, there are 2 forms of this variety of gangrene; one which is due to the action of *Bacillus aerogenes capsulatus* alone and is not accompanied by inflammatory appearances. There is little tendency for the condition to spread until the system is used up and can no more resist the invasion of the germ, and then the disease progresses most rapidly. The other form develops as the result of a mixed infection and is accompanied by marked inflammation and assumes from the start a most progressive nature. Although this gas-producing gangrene is a very severe infectious disease, the prognosis is today not necessarily an unfavorable one, as was the case not many years ago. The treatment should consist in the opening of all suppurating foci, in the early removal of all necrosed tissue even to amputation when called for, and thorough disinfection of the neighboring tissues. If this plan is strictly carried out, recovery should be obtained in the majority of cases. [G.B.W.]

2. Hematologic Examination. ERNEST BECKER.
3. The Means Whereby the Organism Poisons Itself. ALEXANDER ELLINGER.
4. A Chair Sieve. I. BOAS.
5. Appropriate Examination of the Chest with the X-rays and Some Results. LEVY-DORN.

1.—Holzknecht says that it is impossible to obtain satisfactory radiographs of bodies in the esophagus when the transillumination is strictly anteroposterior. If, however, the patient and apparatus are so arranged that the light is transmitted obliquely, *i.e.*, from the left behind towards the right in front, the shadow cast by the spine falls to one side of the line of the esophagus, so that foreign bodies in the latter are projected against a clear field. He makes use of this fact to diagnose strictures of the esophagus in the 3 following ways: 1. The patient swallows a mixture of 2 gm. of bismuth subnitrate in 100 gm. of water. If there exists a tight stricture the water is stopped at the seat of constriction and the bismuth settles against the walls of the esophagus where by the above method it is readily demonstrated by the x-rays. 2. When the stricture is not enough stenosed to give positive results by the first method, the patient may be made to swallow 1 gm. of bismuth in the form of a wafer while the surgeon is watching the chest with the fluoroscope. If the result is positive, a number of dark spots will be seen either stopped and remaining in the same position for some length of time or else moving slowly downwards through the stenosed esophagus. 3. When both of the above methods fail because of the larger caliber of the stricture, the patient should swallow a bolus of food, something which the patient knows from experience will lodge, and then swallow on top of this the bismuth mixture as suggested in the first method, and the use of the x-rays will complete the diagnosis. [G.B.W.]

—Two cases of very mild typhoid showed **leukopenia** up to the beginning of convalescence, when the normal relations immediately began to establish themselves. A third very severe case, which ended fatally, also showed marked leukopenia followed by leukocytosis of high degree upon the occurrence of nephritis and bronchopneumonia. Eosinophile cells appeared only a few days before the fatal nephritis came on, hence the presence of eosinophiles is not

a very important prognostic sign. The examination of the blood is of much importance in the diagnosis between typhoid pneumonia in some cases. A case exemplifying the importance in diagnosis between sepsis and typhoid is detailed also. In **syphilis** a moderate **leukocytosis** chiefly consisting in an increase of lymphocytes was found in 2 cases, while in a third case the lymph glands were not distinctly affected. In 1 case of pernicious anemia, postmortem showed the presence of 2 *Taeniae saginatae*. Becker considers it rather probable that the taeniae stood in direct causal relation with the anemia, probably through the ultimate production of intestinal putrefaction. In 1 case of pernicious anemia the red cells were reduced to 284,000 before death. In a case of severe secondary anemia which simulated pernicious anemia the red cells were reduced as low as 680,000, and megaloblasts appeared in the blood. The necropsy showed a widespread tuberculosis of the mesenteric glands, intestines, and suprarenal bodies. The chief cause of the severe anemia was considered to have been involvement of the mesenteric glands, which hindered the flow of the chyle in the larger lymph-vessels. This case is considered unique. In a case of post-hemorrhagic anemia shortly after hemorrhage, all the elements of the bone-marrow, even eosinophile myelocytes were seen. Nucleated red cells were seen in large numbers, but soon vanished. In lead-poisoning Becker has found the granulations described by Orawitz. There was, however, a decided reduction in the reds. Polymorphonuclear leukocytes were much increased, due, he thinks, to the irritation of the bone-marrow by the anemia. The lymphocytes were normal. In a new attack of colic, a patient that had presented this appearance but whose blood had become normal, returned to the hospital with a leukocytosis of 21,000, 90% of the leukocytes being polymorphonuclear. In a number of cases which had previously had lead colic but were admitted for other complaints, no changes in blood could be found. [D.L.E.]

3.—Ellinger gives a useful review of the chemic methods of freeing the organism from poison. He first discusses the oxidation of acids to harmless products in acid **intoxication**; acid production exists normally, but becomes pathologic only when oxidation fails. Reduction processes are not common; they are, however, more frequent when combined with synthesis. As examples of the occurrence of synthesis, one may mention the production of hippuric acid when benzoic acid is given; there are other instances where more poisonous substances are transformed into nonpoisonous bodies by uniting with glycoli. Another very common synthetic process, and one which is frequently discussed, is the synthesis of phenolindol and statol, after oxidation, with sulfuric acid, subsequent to which they are eliminated in the urine as the ethereal sulfates. The pairing of glycuronic acid is also probably an antidoting process. The production of urea from ammonium carbonate is another important example, the process in this case taking place chiefly or entirely in the liver. Long has shown that hydrocyanic acid may be completely neutralized by the injection of sodium thiosulfate—a further example of synthesis in the body. A very important clinical example is the use of alkalies in diabetic coma. [D.L.E.]

4.—Boas describes the instrument which he has made for the separation of mucus, food particles, etc., in the feces. [D.L.E.]

5.—Levy-Dorn considers that, in **examining the lungs**, the best results are obtained during deep inspiration, except in the examination of the apices, when, on deep inspiration, the clavicles are so elevated that they interfere with the examination of the apices. Moderate inspiration is best in this case. [D.L.E.]

September 13, 1900. [26. Jahrg., No. 37.]

1. Prophylactic and Curative Effect of Urtropin. ZAUDY.
2. Pathogenesis of Staphylococcus Quadregeminus Czajlewski. GEHR. KIESERIEZKY.

4. First Aid Through the Laity in Lime or Plaster Injury to the Eye. H. G. STUTZER.
5. Healed Tuberculosis of the Peritoneum in Children. CASSEL.

1.—Zaudy describes a case of paraplegia in which there

was prostatic abscess and in which the urethra was infected and the perineum had become largely infiltrated with pus. A catheter was used frequently from necessity, and yet in spite of every opportunity being given for infection of the bladder and higher urinary tract the postmortem showed only slight redness of the mucous membrane of the bladder, and above this point no changes except slight hemorrhage. He attributes the lack of infection to the use of **urotropin**. [D.L.E.]

2.—The author describes a case in which without any definite history excepting smallpox and dysentery, the latter being followed by chronic intestinal catarrh, an abscess of a cervical gland developed. This was opened, and the pus showed a staphylococcus which in all its characteristics was identical with **Staphylococcus quadrigeminus** of Czaplowski. [D.L.E.]

3.—Pagenstecher reports a case of **mental delusion following a slight accident** and which ended in the death of the patient. A perfectly healthy and strong man inflicted a slight wound on the finger with a pen and believed that he had poisoned himself with the ink. So sure was he that he poison his blood that he could feel the pain ascending up his arm and begged the attending physician to amputate his arm at once. He had fainting spells and spent a most wretched night and in the morning following the injury he was delirious and raving, but had a good pulse and no fever. The patient could be roused by questioning and generally gave sensible answers, but continually referred to his coming death and to his, to be bereaved, family. After some persuasion he became quiet and had a short sleep, but soon, 20 hours after the accident, he broke into a profuse sweat, just as though the crisis to the disease had been reached and he seemed greatly benefited thereby. From this on there was little change in his condition until he died, 32 hours after he pricked his finger with the pen. The postmortem gave absolutely no light as to the cause of death, and all examinations for the signs of any infection were negative. Pagenstecher also reports 2 more cases of delusions following injuries, but which fortunately resulted in recovery in a day or so. [O.B.W.]

4.—Stutzer says that when an **eye** has been **injured by lime** the best method of treating the condition is to immediately cleanse the eyes with copious washings of clean water which should be kept up for a considerable length of time. This is really a "first aid to the injured" method, as it can be readily carried out by the patient's fellow workers. It can easily be done by one man holding the injured eye open while another with a clean glass and clean water washes the eye until no particles of mortar can be seen therein. [O.B.W.]

5.—Cassel reports 3 cases of **tuberculous peritonitis** in children, which are of especial interest in that the cases demonstrate absolutely the possibility of curing this disease through operative interference. Two of the cases after 4 years and one after 3 years were perfectly well and had the patients developed in a normal manner. In all the cases a piece of the diseased peritoneum had been excised at the time of the operation and the tuberculous nature of the malady proved by microscopic examination. Cassel also goes over the subject of tuberculous peritonitis in children in a rather thorough manner, basing his remarks on the results obtained in 18 cases coming under his own care and on the theories and ideas of his contemporaries. [O.B.W.]

September 20, 1900. [26. Jahrg., No. 38.]

1. The Neuron in Anatomy and Physiology. MAX VERWORN.
2. The Theory of Infection. HUGO MARX.
3. A Case of Disseminated Actinomycosis with Localization in the Brain. W. NIKITIN.
4. The Reduction of an Anterior Dislocation of the Shoulder According to Riedel. GRAEF.
5. Improved Urine Separator for the Collection of Separated Urine from Both Kidneys in Women. ALFRED EGON NEUMANN.

1.—Verworn gives a somewhat extensive review of the **neuron theory**, and the work which has recently been done in favor of it and against it. He ends by stating that recent work has not served to upset this theory. He considers the different arguments against it to touch only the

unimportant points of the theory, the essential element of the theory being in the acceptance of the ganglion-cell body with its processes and dendrites as a cellular unity. He considers it a secondary question as to whether the neurons merely come in contact with each other or are at times actually united by cellular bridges. Even in case the latter were true it would not upset the neuron theory. The only testimony that would do this would be the demonstration that what we have considered neurons are really several cells. He considers, however, that the neurons vary greatly in various places according to their functions. [D.L.E.]

2.—Marx refers to the fact that he and Woihte have previously stated that they consider the **Babes-Ernst bodies in bacteria** a condensation of the enchromatic substances of the bodies of the bacteria. They are found in greatest number in bacteria derived from animal bodies or secretions. The further the bacteria are by culture removed from this degeneration the fewer of these bodies do they contain. Their frequency increases when the microorganisms are again carried through animal inoculation. These bodies are closely related to the division processes of bacteria. The conclusion to which Marx comes after reconsidering these statements is that in the number of the Babes-Ernst bodies, one has the measure of the virulence of the bacteria. As an example of this he states that in the sputum under normal conditions one finds streptococci which contain these bodies only occasionally, but in cases of erysipelas arising in the mucous membrane of the mouth or throat these bodies at once increase largely in number and are seen in almost every streptococcus. [D.L.E.]

3.—In this case of **actinomycosis**, the first symptom was an irritating cough, which was supposed to be due to chronic pharyngitis. The cough was very variable, sometimes disappearing altogether, sometimes severe with more or less expectoration. Finally, the patient developed a circumscribed bronchopneumonia, but this in turn partially disappeared. Some 6 weeks later the patient came back with symptoms of a cold abscess in the region of the second rib on the left side. This was opened and a fair amount of pus was obtained. The wound granulated but would not heal and later abscesses in various parts of the body developed. The majority of these, however, contained only bloody serum and no true pus. In this fluid the clusters of the actinomyces were found, making the diagnosis easy. The patient improved in many ways but developed signs of cerebral involvement. These were manifested first by spells of dizziness, which gradually grew very marked and more frequent. Finally, these attacks were accompanied by most intense headache, which was generally located in the left half of the head and lasted for a few hours. This pain was accompanied by tetanic convulsions of the left side of the face. Finally paralysis of the face, then of the arm, and lastly of the leg developed, ending in the death of the patient. [O.B.W.]

4.—Graef reports a case of **dislocation of the shoulder joint**, in which after various methods had been tried and had failed to reduce the dislocated joint, the reduction was finally accomplished with ease by the Riedel method. The patient was a young man who had suffered from dislocation of the shoulder several times, and at each time the reduction was only accomplished with great difficulty. At the present time the luxation was anterior and involving as usual the left shoulder joint. The patient was chloroformed, and after much energy had been wasted, the dislocation was still unreduced. Riedel's method was then tried. The surgeon stood on the right side of the patient, and seized the left arm above the wrist,—a short strong pull in the direction of the right side of the pelvis was done, and the head of the bone promptly slipped back into the glenoid cavity. [O.B.W.]

5.—Neuman describes a modified form of the **urine separator** first introduced by him in an article already published. (*Deutsche medicinische Wochenschrift*, No. 43, 1897.) The instrument in its present form consists of two parts, a vaginal portion and a urethral-bladder portion. The part introduced into the vagina presses upon the posterior wall of the bladder, forming a ridge which separates the viscus into a right and left portion, each of which receives the urine from the ureter opening into it. A small tube is introduced into each sulcus, and the urine thus collected is carried off separately into test tubes, thus enabling the physician to examine the urine from each kidney. [W.K.]

Practical Therapeutics

Under the charge of

A. A. STEVENS, A.M., M.D.

Large Doses of Olive Oil in Stenosis of the Pylorus.—Cohnheim (*British Medical Journal*, November 3, 1900), at the recent meeting of the International Congress of Medicine, presented a report on the therapeutic action of olive oil in cases of organic and spastic stenosis of the pylorus and duodenum, and, in consequence of these conditions, gastrectasia. From his observations and experiments he drew the following conclusions: Cases of gastrectasia that do not depend on an organic obstacle but on spasm of the pylorus, following an ulcer or fissure at the orifice of the stomach, are cured or markedly improved in a short time by the introduction of large doses of oil (100 to 250 grs. daily). In the same way cases of pyloric or duodenal stenosis of cicatricial character, accompanied by secondary gastrectasia, are cured in a relative sense by the systematic employment of large doses of oil, that is to say, the patients feel no discomfort provided they avoid all excess. In such cases the resistance caused by the friction is diminished by the mechanical effect of the oil. Cases of relative stenosis of the pylorus and duodenum, which are characterized by continuous secretion and pyloric spasm after the principal meals, are improved or completely cured by the oil. It is well that the oil should be taken or administered through a tube during a more or less considerable period of time, thrice a day in doses of 50 ccm., an hour before meals. If for other reasons this plan is impracticable a dose of oil (100 to 150 ccm.) at the temperature of the body should be given once a day. The use of the oil meets three indications: It causes relaxation of the spasm, it diminishes the friction, and improves the nutrition, since the oil, even in very pronounced stenosis, reaches the intestine and is absorbed. In cases of ulceration the oil acts on the spasm as a narcotic. If it be pure it has no unpleasant secondary effect, it causes neither eructation nor diarrhea; patients take it willingly. In cases of cramp of the stomach of purely nervous character the author has been unable to obtain favorable results with the oil. This fact supplies a means of differential diagnosis between nervous and organic spasm. By means of the oil cure it is possible to relieve a number of cases of pyloric stenosis with consecutive gastrectasia to such an extent that surgical intervention becomes superfluous. Cohnheim therefore thinks it is desirable to try this method of treatment in cases of stenosis of the pylorus before having recourse to operation.

Enlarged Prostate.—Miller (*Scottish Medical Journal*, August, 1900) believes that much can be accomplished in the early stage of prostatic hypertrophy by establishing the habit of emptying the bladder regularly and thoroughly. He concludes that residual urine is due at first to neglect to empty the bladder, and accumulation is due to this becoming a habit. The practical application is that men advanced in years who are beginning to have prostatic symptoms should make a point of emptying the bladder thoroughly. His advice is: After passing water in the usual way, wait a minute or two and then try again. Practise this as frequently as possible, till only a very small quantity can be squeezed out (5j). When that point has been reached, twice or thrice daily may suffice. This procedure acts in two ways: First, the small residuum of urine that may result from a careless act of micturition is got rid of. In the second place, the bladder tone is improved, and its function restored. Moreover, the habit of completely emptying the bladder is acquired. A still more important result is that the residual urine being diminished cannot possibly increase. The author states that he does not bring this forward as a cure or as a method of preventing residual urine from forming in every case of enlarged prostate. He merely suggests a safe and simple procedure, which has apparently checked the increase of residual urine in several cases, and which may in some others at least postpone the almost inevitable catheter.

Urotropin.—Suppan (*Wiener Med. Blätter*, July 12, 1900) states that urotropin should be employed in every case of urosepsis of the aged with prostatic hypertrophy, in all the nonacute and septic bladder and pelvic catarrhs which are

the consequences of this growth, as also in inflammatory conditions dependent upon atrophy of the prostate, neoplasms, diverticulæ of the bladder, and stricture. The author speaks highly of the value of urotropin in cystitis. He has had excellent results from its use in 17 cases of cystitis, which were gonorrheal, or associated with a pure bacteriuria. He has also seen rapid and permanent effects from the drug in 7 cases of obstinate phosphaturia appearing after long-continued diarrhea.

Snake-bite.—McFarland (*International Medical Magazine*, September, 1900) summarizes the treatment of snake-bite as follows: Stop immediately the circulation in the bitten member or part of body, so as to prevent absorption of the poison. Incise and enlarge the fang wound freely and suck forcibly to extract the poison—the suction may be accomplished with a cupping-glass or with the mouth, the poison being harmless when swallowed. Inject hypodermically 3 to 6 drops of a fresh 10% aqueous solution of calcium chlorid into about a dozen areas around the wound. Gold chlorid is just as effective, but it is too expensive. Potassium permanganate is of little value. Give strychnin hypodermically to stimulate the respiratory center. Whisky should not be given at all, or only in very small doses, because an excess of alcohol still further depresses the heart already depressed by the venom. Immediately inject 10 to 20 cc. (2½ to 5 drams) of antivenomous serum and repeat these injections frequently. People living or going into regions where there is danger of snake-bites should carry a bottle of antivenomous serum with them.

Transfusion.—Annandale (*Scottish Medical and Surgical Journal*, September, 1900) draws the following conclusions in regard to transfusion: That it may be a valuable aid in saving life in the case of patients suffering from serious loss of blood, provided they show no signs of reaction after the ordinary means have been carefully tried. That the best form of transfusion for ordinary use is the injection of human blood mixed with a solution of sodium phosphate, and kept at a proper temperature, so as to prevent clotting. That if the former method cannot be properly carried out, the injection into a vein of saline solution (sodium chlorid) is the next best procedure. That intraperitoneal injections of warm water, or warm saline solutions, are most likely to be useful in cases in which the abdomen has already been opened, for without an opening there is always a risk of injuring the intestines or other internal organs with trocar and canula. That injections of warm water, or of warm saline solutions into the rectum, or into the cellular tissues, is a safe and simple procedure, which may be usefully employed in any sudden emergency.

Organotherapy in Gynecological Therapeutics.—Jack (*International Journal of Surgery*, October, 1900) draws the following conclusions from his experiments and the study of the literature: Thyroid extract is one of our most reliable vasoconstrictors, and as far as its gynecological application is concerned, should be limited to hemorrhages, and those especially in which the epithelial elements of the endometrium are concerned. Mammary extract controls the hemorrhages from fibromas, reduces the size of the tumors, and in some cases causes their disappearance, and should be preferred to the thyroid extract, which does the same thing, in treating fibromas. Parotid extract is the best remedy yet brought out in the treatment of dysmenorrhea, relieving as it does the aches and pains of ovaritis and improving nutrition. Pelvic exudates soften and are often absorbed. Menstruation becomes regular and less in amount when excessive and shorter in duration. The headaches and nervousness so often accompanying these cases are as a rule cured, health and spirits revive, and, indeed, its action here can be denominated nothing less than specific. Ovarian extract is indicated in all cases of menopausal nervous symptoms, or when for any reason it is desirable to increase the flow from the uterus. It is now known almost beyond doubt that the ovary has, besides its function of ovulation, another almost as important, that of internal secretion, and that, like the thyroid, it secretes an active oxidizing agent, spermin, that aids in the metabolism of the blood. Marked decrease in the elimination of phosphates has been observed after ovariectomy.

Cacodylate of Iron.—In the Section of Therapeutics at the recent International Congress of Medicine P. Lereboullet (*British Medical Journal*, October 13, 1900) said that cacodylic medication in the form of cacodylate of soda having proved useless as a remedy for chlorosis and chloranemia, Gilbert and he had used cacodylate of iron in the treatment of these affections. They injected under the skin ferric cacodylate, a very soluble and only slightly toxic salt, in a solution dosed at 3 cg. per ccm., they also gave it by the mouth in the form of drops to be taken before meals. The daily doses varied from 3 to 10 cg. hypodermically, and from 5 to 30 cg. by the mouth. Both methods of administration proved to be alike free from inconvenience. In no case have they observed local or general disturbances; in particular there have been none of the renal complications which are so frequent after injection of other iron salts. Cacodylate of iron is indicated in affections when one has at the same time to counteract the diminution in number of the red corpuscles, and the fall in the amount of hemoglobin (chlorosis, chloranemia, lymphadenia, leukemia). Tuberculous chloranemia, provided the pulmonary lesions are not too far advanced, seems to be specially benefited by this treatment, which has never caused congestive phenomena or hemoptysis. Albuminuria, which is frequent in such patients, is not a contraindication, but rather the contrary. In 5 cases the kidney lesions underwent marked improvement after the injections.

Injection of Formalin Successfully Employed in the Treatment of a Sarcoma of the Nasopharynx.—Thompson (*The Laryngoscope*, September, 1900) reports a case of a man, aged 50, suffering from a sarcoma of the posterior wall of the nasopharynx, in which injections of formalin proved remarkably successful. The diagnosis was confirmed by microscopic examination. The patient's general condition forbidding operation, 25 minims of a $\frac{1}{2}$ % solution of formalin was injected into the tumor twice a week. The blood-supply of the tumor being cut off by the injections, removal by the forceps soon became possible. After 14 months there had been no recurrence.

Antidotes for Iodism.—Montgomery (*Medical Age*, October 25, 1900), states that belladonna is far the best drug to relieve the coryza-like effects of potassium iodid, and that he generally gives 5 drops of the tincture with each dose of the iodid. Any other preparation of the drug, such as atropin, may be used. It may also control some other forms of iodism. Fowler's solution is undoubtedly the best associate drug to use when potassium iodid causes indigestion. It is best given in 1 or 2 drop doses, just as one would prescribe it for indigestion. Besnier advises giving it in the proportion of 1 drop to each 15 grains of the iodid, but it is doubtful if such a rule has any real value. It would appear that Fowler's solution at times does more than merely correct the indigestion, for Sillock (*British Medical Journal*, October 24, 1895) has reported a case in which it prevented iodic purpura.

Hay Fever.—

R.—Acetic acid.....	4 minims.
Resorcin	3 grains.
Sodium chlorid	8 grains.
Water.....	2 ounces.

Use as a wash for the nasal passage.—[*Merck's Archives.*]

The Treatment of Gonorrhea in the Female.—Gardner (*Montreal Medical Journal*, April, 1900), writes as follows concerning the treatment of gonorrhea in the female: In the acute stages the patient must be kept in bed. The diet should be unstimulating, the bowels regulated by saline purgatives, and warm hip-baths and frequent soothing irrigation of the genitals employed. The use of linseed tea by irrigation and douche is very grateful to the patient. The acute stage having passed, germicidal douches of permanganate of potash 1:5000, bichlorid of mercury 1:5000 to 1:2000, or formaldehyd 1:4000 to 1:2000, may be employed. The toxic sublimate must be cautiously used. For the best results the vaginal douche must be administered in the dorsal position on the bedpan. If the patient lie still for a time afterwards, there is in many women a tendency for a pool of the solution to remain in the vagina, from which it may be absorbed. The sublimate douche should therefore be followed by a small quantity of warm water. But the

vaginal douche must be considered as merely accessory to the thorough application to the whole of the affected surfaces of the most effectual of all remedial agents, silver-nitrate solution in strength of from 20 to 60 grains to the ounce of water. This cannot be done thoroughly in any other way than with the patient in the Sims position, through the Sims speculum. The surface to be thus treated must be wiped clean and dry, and the solution thoroughly applied by the swab with pressure till every part is whitened. If protargol and argonin be equally efficacious, they will be valuable acquisitions. They may be used in strength of from 1 to 3%. The urethra, and especially the Skene's tubules, the ducts of the Bartholin glands, and the cervix must be treated by applications of the same remedies. The urethra and cervical canal may be best treated by instillation of the solutions, Skene's tubules, and Bartholin ducts, with a small, slender-nozzled syringe. For all the accessible areas affected by the disease the use of a 5 to 10% solution of ichthyol glycerin is advocated by Bumm. This remedy may be used on pledgets of gauze or tampons left *in situ* in the intervals of the applications of the silver salts. In the treatment of the uterine cavity, in all but the most advanced chronic stage, local treatment by curetting, douches, etc., must be avoided. In the early stage, instrumentation of the cavity of any kind is very apt to lead to extension to the tubes and ovaries.

Therapeutic Use of Thymus.—In the Section of Therapeutics, at the recent International Congress of Medicine, Blondel (*British Medical Journal*, October 13, 1900) read a paper on this subject. He said, it was generally admitted that chlorosis depended on an autointoxication, in the production of which the absence, or at least the insufficiency, of the internal secretion of the ovary played an important part. Hence was derived the idea of administering preparations of ovary as a remedy for that affection. Previous researches having satisfied Dr. Blondel that there was an almost absolute functional analogy between the thymus and the genital glands, he conceived the idea of employing preparations of thymus instead of ovary in the treatment of chlorosis. In 15 patients treated in that manner, he had seen marked amelioration of the general condition take place within a few weeks, whilst at the same time appetite and sleep returned, the color was restored, the number of red corpuscles was notably increased, palpitations and jugular *bruit* disappeared. In addition to this, Dr. Blondel followed up the researches of Owen on the administration of thymus in Graves' disease. He had treated in this manner 4 patients with very satisfactory results. In a few weeks, the circumference of the neck diminished by several centimeters, the pulse fell from 120 or 130 to 80, tremor became less, etc. Lastly, in 10 nurslings, in whom development was slow and imperfect—in some owing to premature birth, in others to congenital debility—the administration of thymus caused a regular rise in the weight curve which till then had been stationary, or even on the down grade. In all these cases, he used lamb's pancreas, which is much cheaper than that of the calf. In order to prevent any feeling of disgust, he first peptonized the thymus. He gave his patients from 1 to 2 grams of thymus-peptone daily. A peptone of ordinary meat given to the same patients in equivalent doses produced no appreciable effect.

Potassium Permanganate in Opium and Morphin Poisoning.—Moor (*The Permanganate Treatment of Opium and Morphin Poisoning*, 1899) in this monograph reviews the reported cases of opium poisoning treated with potassium permanganate, and emphasizes the following points in the treatment: One grain of the antidote in 1 ounce of water *per os* for each grain of morphin. One grain of potassium permanganate in 1 ounce of water for each 10 grains of opium. One grain of the antidote in 1 ounce of water for each dram of laudanum. If the quantity of poison injected cannot be ascertained, 8 or 10 grains of the antidote dissolved in an ordinary glassful of water should be given at once, and this dose repeated once or twice at intervals of 30 minutes. A weak permanganate solution, about 1 grain to a tumblerful or half a tumblerful of water, should be administered every 30 minutes during the entire stage of opium narcosis, and even for some time afterwards at intervals of 1 hour. One grain of permanganate dissolved in 1 teaspoonful of water should be injected hypodermically every 30 minutes, with simultaneous gentle massage near the site of injection.

FOREIGN BODIES IN THE AIR-PASSAGES.

By FRANCIS T. STEWART, M.D.,

Surgeon to Out-Patient Department, Pennsylvania Hospital; Associate Professor Surgery, Philadelphia Polyclinic.

AVOIDABLE death, especially when so imminent as from foreign bodies in the air-passages, is well calculated to excite acute sympathy and energetic action in him who has by careful forethought and training prepared for it, and to appall and stupefy one who knows not how to avert it. Robert Liston's "Learn to look boldly on the open mouths of arteries" may have its correlative in "Learn to look boldly on impending death from asphyxia." That every physician should be able to cope with an extraneous substance in the respiratory tract is irrefutable from the importunate nature of the accident. The following cases occurring in the Pennsylvania Hospital are reported with a belief that all such records are of value to the profession.

CASE 1.—T. C., aged 46 years, was admitted August 15, 1872. During a fit of mania the patient pushed a haircomb down her throat. Intense dyspnea followed. The smooth portion had been introduced first so that the teeth caught in the fauces when extraction was attempted. After some difficulty one side of the comb was seized with strong forceps, version accomplished, and delivery effected. The comb measured $5\frac{1}{2}$ by 7 cm.

CASE 2.—C. G., aged 18 years, was admitted February 26, 1888, having been ill 4 weeks with symptoms of pneumonia. Soon after admission the expectoration became profuse, dark in color, and very offensive. Hemoptysis was frequent. He died on the eighty-fourth day of disease, after a copious hemorrhage. On postmortem examination the right lower lung was found to be solid and densely adherent. At its base posteriorly there was a cavity the size of a walnut, full of recent clots in which were found 4 small pieces of evergreen. A sprig of evergreen $\frac{3}{4}$ of an inch long projected from one of the bronchioles into the cavity.

CASE 3.—E. R., aged 16 years, was admitted December 26, 1888, during a convulsion. A history of epilepsy dating back 6 years was obtained. On recovering from the fit the breathing was limited and stridulous with prolonged inspiration. Asthmatic treatment was instituted. During the night he was awakened by violent cough and dyspnea, which resulted at the end of 15 minutes in the expectoration of a piece of raw apple, giving instant relief.

CASE 4.—J. L., aged 65 years, was admitted January 1, 1891, suffering distressing respiratory embarrassment subsequent to the inspiration of a morsel of meat. Manipulations for examining the larynx caused severe coughing, during which the offender was expelled.

CASE 5.—L. M., aged 2 years, was admitted April 25, 1891, after accidentally lodging a jackstone in the larynx. It was removed from above by long forceps.

CASE 6.—S. H., aged 3 years, was admitted September 2, 1892. His mother had found him in the back yard bleeding from the mouth, and unconscious. A low tracheotomy was immediately performed. The patient died the next day. The postmortem revealed a portion of glass bottle wedged in the larynx so tightly that the vocal cords were torn in its removal. The condition of the lungs is not mentioned in the notes, but one would infer that the blood, which must have trickled into the bronchi from the wounded larynx, contributed largely to the fatal issue.

CASE 7.—On July 24, 1895, a tramp, 42 years of age, was brought to the hospital from a railroad depot by the ambulance. He would say nothing more than that he had been ill 2 days after a wetting, and that he had spat a little blood. Objectively there were fever, cough, dyspnea, cyanosis, rapid pulse, patches of impaired percussion-note over the chest with numerous small, bubbling rales. He died 2 days later. At the postmortem both lungs were found congested, with many areas of collapse and consolidation. Just above the

bifurcation of the trachea were several small ulcers. In the right bronchus, near the tracheal opening, were 3 pieces of coke, weighing $19\frac{1}{2}$ grains. At a point corresponding to the position of these stones were four gangrenous ulcers. Two stones had been arrested in the left bronchus. Dr. F. A. Packard, who exhibited the specimen before the Philadelphia Pathological Society, theorizes that the patient, while riding on the truck of a freight train, had fallen asleep with the mouth open, when a shower of coke from the roadbed flew into the dilated glottis. The fragments must have entered almost simultaneously, as spasm would have otherwise precluded the inhaling of more than the first piece. It is scarcely possible that the accident happened 5 distinct times. This case emphasizes the necessity for a systematic splitting of the trachea and bronchi in all autopsies. A careless pathologist would have been content on seeing the bronchopneumonia, and would not have found the real cause of trouble.

CASE 8.—B. H., aged 15 months, was hurried to the hospital May 26, 1898, with absolute apnea. Immediate tracheotomy and artificial respiration proved futile. After death a collar-button, its shoulder resting on the vocal bands, was discovered blocking the rima glottidis.

CASE 9.—P. M., aged 6 years, was admitted November 27, 1898. One week before, he had inhaled a grain of corn, barely escaping suffocation at the time. Since then there had been repeated paroxysms of cough and dyspnea. He had been treated with emetics and by succussion without success. The patient pointed to a spot corresponding to the beginning of the right bronchus as the seat of trouble. A few moist rales could be heard over the right lung where the resonance was impaired and the breath-sounds feeble. While in the Receiving Ward he suddenly coughed and became asphyxiated. The windpipe was immediately opened, but respiration could not be induced by artificial means. A finger passed into the trachea as far down as the bifurcation did not meet with the foreign body and it could not be felt above. The boy was grasped by the heels, the head pendant, and violently shaken without bringing the corn to light. An autopsy was forbidden.

CASE 10.—During the year 1899 a man who had suddenly fallen to the floor unconscious while eating his evening meal was admitted to the hospital. In the pharynx and upper part of the larynx was lodged a large piece of meat. He could not be resuscitated.

CASE 11.—During the same year a valuable spaniel was brought to the hospital to be examined by the x-ray, the owner fearing he had swallowed a needle about one week before. There had been frequent attacks of cough and dyspnea. The fluoroscope revealed the needle just below the cricoid cartilage situated transversely to the long axis of the neck. An incision was carried down to the trachea from which projected a threaded needle. It was extracted and the dog promptly recovered.

CASE 12.—A. P., aged 64 years, was admitted May 10, 1900. He had become unconscious while eating lunch. The bystanders supposed he had a "stroke." He was dead when he reached the hospital. The upper part of the larynx was filled with meat weighing 6 drams.

Anything small enough to enter may find its way into the air-passages. In the above may be found: a comb, sprigs of evergreen, a piece of raw apple, morsels of meat, jackstone, portion of glass bottle, fragments of coke, collar button, grain of corn, and a threaded needle. It is unusual to have more than one foreign body in the air-passages. In 2 of our cases (2 and 7) there were 5 fragments. In 1000 cases collected by Weist² the most frequent substance was a grain of corn, 177 cases, followed by watermelon seed, 109 cases; bean, 90 cases, and grain of coffee, 59 cases.

Congenital defects or destruction of the epiglottis by ulceration, certain diseases like bulbar paralysis, and unconsciousness from any cause, would predispose to the intromission of extraneous substances. Agnew³ relieved symptoms of suffocation in one of his patients by dislodging a displaced epiglottis from the top of the larynx. The danger of holding tacks and similar articles in the mouth, and the danger of blowing "spit

balls" and "putty balls," indulged in by some children, may be here mentioned.

Foreign bodies may be introduced through the glottis or through an artificial opening in the trachea. They may penetrate from without as a bullet, needle or other sharp body. Gross⁴ quotes the following case: A small boy, while amusing himself cracking a whip, was seized with respiratory difficulty. The first surgeon who saw him examined the throat, and finding nothing abnormal, resorted to a full bleeding. When De la Martiniere was called he perceived a small, red, indurated spot just below the cricoid cartilage. On making an incision a small brass pin, which, as was afterwards ascertained, had been attached to the end of the lash, was found penetrating the trachea. Gross characteristically remarks, "One such case is enough to immortalize a surgeon." They may ulcerate into the respiratory tree from the esophagus, mediastinum, or one of the subphrenic organs, stomach, colon, liver or spleen. Edwards⁵ records a remarkable case of suffocation from impaction in the rima glottidis of a bronchial gland which had ulcerated into the respiratory tree. Duroziez⁶ reports the discharge of an echinococcus of spleen through the bronchi. They may be admitted through the chest-wall, and they may be formed in the lung itself, the so-called lung stones. There is on record the case of a soldier who 4 months after a gunshot wound of the chest coughed up a fragment of one of his own ribs. In Case 11, the needle was probably partially swallowed and afterwards penetrated the trachea.

If the substance is not arrested in the larynx either between the cords or in one of the ventricles it usually descends into the right bronchus, unless it be of such a nature as to catch in the walls of the trachea. The order of the frequency of lodgment is, right bronchus, larynx, trachea, and left bronchus. The right bronchus is more propitious for the entrance of anything dropping into the windpipe because of its greater diameter and because the bronchial septum is situated to the left of the median line. In our cases there were 6 in the larynx, 2 of which, Cases 10 and 12, were partially in the pharynx; 2 fell into the right bronchus, Cases 2 and 9; 1 was lodged in pharynx; in Case 7 both bronchial tubes were blocked by coke; and in 1, Case 3, the exact site cannot be determined. They may be expelled by mouth or through an artificial opening; they may be coughed into the pharynx and swallowed; and they may gain exit by ulceration through the chest-wall. Expulsion was accomplished in Cases 3 and 4 only. They may be expelled instantly or after months or even years. Bartlett⁷ reports a case in which a piece of bone was ejected after 66 years. Case 2 must have retained the evergreen at least 84 days. Inflammation usually follows retention (Cases 2, 7, and 9), either destroying the patient or walling in the offending material. Vegetable substances may swell and sometimes sprout.

Death is due to asphyxia from complete blocking of the respiratory channel by the exotic mass or violent spasm of the glottis; or is the result of the subsequent inflammation. Rarely hemorrhage may cause a fatal issue. Rokitsky⁸ contributes a case in which the point of an inhaled dart pierced the innominate artery. Five of our deaths were due to asphyxia, three of which were instantaneous; and two were due to inflammation. In 1674 cases collected by Weist,⁹ Gross,⁴ and Durham⁶ the mortality was 27.53%. L.

The morbid anatomy is that of the resulting inflammation and is often associated with atelectasis.

If the foreign body is large enough to completely block the air-channel death occurs instantly; if smaller there is great dyspnea, violent cough, lividity of the countenance, writhing of the patient, and partial insensibility. Asphyxia in these cases is due to spasm of the glottis. Unless the extraneous matter be expelled there ensues a variable lull, followed by a recurrence of the symptoms which is usually repeated until the alien be gotten rid of or descends into the lung. Although the symptoms are characteristic, the diagnosis is often hard to make, especially if the patient be unconscious or be a child from whom no history can be obtained. They may be mistaken for asthma (Case 3), pertussis, epilepsy, diphtheria, cardiac disease, spasmodic croup, laryngismus stridulus, edema, and ulceration of the larynx, for the laryngeal crisis of locomotor ataxia, and for the omnipotent "worms." After expulsion the symptoms persisting, owing to irritation, may give rise to doubt.

The diagnosis is usually made from the history given by the patient or the patient's friends. In children a foreign body should always be thought of if there be respiratory difficulty, especially if there has been previous absolutely perfect health with a sudden onset of symptoms. If there be an obstruction the breathing will be slow compared with that of disease, inspiration will be difficult and prolonged with retraction of the lower chest, the respiratory murmur will be diminished or absent on the corresponding side if there be impaction in a bronchus, the pulmonary resonance, however, being normal. Sometimes the foreign body may be heard in the trachea rising and falling with each respiration. There will be absence of fever and the symptoms intermittent, the child appearing happy in the interim. A laryngoscopic examination should be made, and as blocking of the esophagus may cause suffocative symptoms, a probang may clear up the uncertainty. It may be necessary to administer a general anesthetic to accomplish this. In the unconscious, if there is doubt as to its nature and especially if it occur during a meal, a finger may be passed into the throat and the larynx and the trachea may be inspected directly with an autoscope. In Cases 10 and 12 the patient became unconscious while eating in a public restaurant, the cause of trouble was not suspected by the bystanders in either case.

When the infective sequels from irritation of the irrelevant material have become established, without a guiding history the diagnosis may well nigh be impossible. Cases 2 and 7 are examples.

The chronic cases would have to be differentiated from inflammatory diseases from other causes, and from any other etiologic factor either extrinsic or intrinsic in a chronic laryngeal, tracheal, or bronchial stenosis. As extrinsic causes may be mentioned cicatricial contractions, localized emphysema, enlarged thyroid and thymus, extensive pericardial exudate, dilation of the left auricle, disease of the clavicle, sternum and vertebrae; and cervical or mediastinal cyst, abscess, neoplasm, aneurysm, and enlarged lymphatic glands. Intrinsic causes are malformation, neoplasm, inflammatory thickening, intussusception of the trachea, paralysis of the posterior cricoarytenoids, longitudinal involution of the trachea after tracheotomy; adhesions of the epiglottis, between vocal bands, between the arytenoids; cicatrices, syphilitic, tuberculous, traumatic; and cica-

trices following certain diseases as scarlatina, diphtheria, variola, rubeola, and enteric fever.

The characteristic inspiratory dyspnea is sufficient to establish the diagnosis of stenosis. If the voice is altered with pain and rhoncus in a larynx which rises and falls with each respiration, the lesion is probably in the larynx. Examination with reflected light would confirm the diagnosis. Dysphagia has been observed in some cases and according to Gerhardt⁷ the head is apt to be held backward in laryngeal constriction, and slightly depressed, with extended neck, in tracheal constriction. The respiratory murmur would be diminished over both lungs in any constriction above the tracheal bifurcation, which constriction, even though below the larynx, may also weaken the voice, owing to the lessened column of air impinging on the vocal bands. Fixed pain and rhoncus together with visual examination through the mouth would locate the stricture in the trachea. Cohen¹ has recognized stenosis due to aneurysm of the arch of the aorta laryngoscopically. The sound has been abandoned. Narrowing of a bronchus would be recognized by physical examination of the chest, although Killian⁸ was able to directly inspect the larger bronchi through a long speculum introduced through the mouth. Diminished inspiratory dilation of one lung as evinced by inspection, palpation, and mensuration, with diminished vesicular murmur and vocal fremitus, and retention of resonance could only be caused by narrowing of the bronchus or pneumothorax. A whirring rhoncus of the same character and intensity, and occupying the same place on different examinations, together with fixed pain and palpable thrill over the spot corresponding to a bronchus, would definitely settle the point of constriction.

To determine the nature of the lesion the history and laryngo-tracheoscopic examination are all-important. The diagnosis of foreign body would be made by excluding the other causes of obstruction. Copious offensive expectoration is manifestly not characteristic of foreign body, as some have held. An x-ray plate might facilitate the differentiation, especially if the foreign body be metal.

In the treatment of extraneous substances in the air-passages, emetics, sternutatories, inhalations, liniments, ointments, and titillation of the larynx should have no place. In a great emergency a knife may be thrust through the cricothyroid membrane, if more time, a low and rapid tracheotomy should be performed, if seen during the quiescent period a careful examination should be made. When above the vocal bands the body may be removed with finger or forceps, when below this point and irregular or jagged, permanent injury may be done the vocal bands by forcibly dragging it out. Killian⁹ removed a fragment of bone from the right bronchus through the mouth, after locating it with a bronchoscope. If impossible or injudicious to extract it from above, preparations should be made for tracheotomy and the patient inverted and succused with a pillow. This may be successful, especially when the alien is small, round, and heavy. Inversion without adequate means for immediately opening the trachea is dangerous because of the possibility of death from impaction in or spasm of the glottis, the foreign body suddenly striking the larynx from below. Case 9 perished from glottis spasm. If inversion fail the trachea should be opened low down and efforts made to find and remove the offending material even though the symptoms be not urgent. Delay is perilous because of

the imminent jeopardy of death from impaction or convulsive closure of the glottis, or from destructive inflammation. Cases 2 and 4 died as a result of lung inflammation.

Weist² believes that tracheotomy should not be performed if there are no dangerous symptoms. He has collected 1,000 cases, which have been carefully and exhaustively analyzed. Of these, in 599 in which no operation was performed, 23.21% died. In 338 which were treated by operation, 27.52% died. Sixty-three cases were excluded. In 93 deaths after tracheotomy the foreign body was not removed in 73, or 78.30%, thus leading to the conclusion that the wound adds greatly to the danger when the bodies are impacted in the bronchi, or are inaccessible. Durham⁵ tabulates 554 cases. Of 271 not operated on, 42.5% died, and of 283 undergoing operation, 24.8% died. (This includes 3 cases of extraction from above and 12 cases of inversion without tracheotomy). Of 167 tracheotomies, 37, or 22.15%, died, the author stating that most of the fatalities were not due to the operation, but to delay in its performance or to some deficiency in the subsequent treatment. Of the cases collected by Gross⁴ in which the particulars are given, 102 (including 4 cases of inversion) were subjected to operation, with a mortality of 14.11%; of 81 not operated upon, 35.91% died; of 723 subjected to operation, 24.48% died. Combining the statistics of Gross, Durham and Weist, there are 1674 cases; in 951 not operated upon, 29.75% died. The statistics of Weist favor the expectant treatment, those of Gross and Durham the operative treatment, the combined statistics slightly favor the operative treatment. There is no evading the accuracy of these figures, but they are unjust. It would be fair to presume that most of the cases tracheotomized in which death ensued would have succumbed by the expectant treatment; ours (Cases 6, 8, and 9) certainly would have. Many are operated upon in the death struggle, and many when grave inflammation is already under way. Recovery is not assured unless the substance be gotten rid of. Years may elapse before a fatal termination.

We are confident that the mortality would be much lower if as soon as inversion fail, tracheotomy were performed. There are a few cases, however, in which no operation would be of service (Case 2 and probably Case 7).

The body is frequently expelled as soon as the trachea is opened; it may be facilitated by turning the patient face downwards or by inversion and succussion. These measures failing, careful search should be made and removal effected with finger, forceps, scoop, hook, probe, or wire. Voltolini⁷ has suggested the use of a powerful magnet to attract bodies like needles and tacks. With a Bigelow evacuator we have been able experimentally to aspirate shot, small fragments of meat, sponge, and similar substances. Gerster¹⁰ removed a bean through a low tracheotomy wound by sucking it into a drainage-tube. Coolidge¹¹ introduced a urethroscope into the trachea through a previously existing tracheotomy wound and by reflected light was enabled to seize a rubber tracheotomy-tube which had lodged in the right bronchus one-half inch below the bifurcation. If efforts are unavailing put sutures or hooks in the wound to keep it open and try again the next day. A tracheotomy-tube would hinder expulsion of the foreign body.

Laryngotomy, because of the danger of injuring the vocal bands, should be performed only when the foreign body is certainly in the larynx and cannot be removed

in any other manner. Pharyngotomy⁷ has been employed to remove a needle from the larynx in one case and a ring in another case. The indications for such procedures must be very rare indeed.

Bryant,¹² in 1895, proposed posterior thoracotomy for foreign bodies in the bronchi. Curtis,¹³ in 1896, put this suggestion into practice. Failing to remove a seed vessel transfixed by a pin from the right bronchus after tracheotomy, he proceeded to attack the bronchus directly through the posterior chest-wall. Portions of the fourth, fifth, and sixth ribs about 3 inches in length were resected subperiosteally, from the tuberosities outward. The periosteum and intercostal muscles were then carefully divided so as not to injure the pleura which was widely detached to give access to the root of the lung, thus making the operation extrapleural. The bronchus was not opened until the succeeding day because of the serious condition of the patient. Forceps introduced into the opening failed to recognize the foreign body which was afterward palpated through the lung tissue. An incision was made through the lung down to the pin which eluded, however, the grasp of the forceps. The operation was discontinued owing to grave symptoms, the patient dying 48 hours later of a previously existing pneumonia. On dissection the pin lay in one of the secondary bronchi, through the wall of which it projected.

If a pulmonary abscess can be accurately localized it may be opened and drained and the irritating body removed or later discharged.

When introduced from without, as a bullet, it should be left alone unless it can be easily extracted or unless it give trouble, when it may be removed if its situation be definitely known.

A TROPICAL RATION.

By J. R. KEAN, M.D.,

Major and Surgeon, U. S. Vols.

Chief Surgeon, Department of Havana and Pinar del Rio, Quemados, Cuba.

[Concluded from page 1089.]

II.—CHANGES IN THE PRESENT RATION TO PROVIDE FOR THE ABOVE DIFFERENCES.

The ration as at present constituted is given in Table I, side by side with the proposed tropical ration.

For a proper study of the ration it seemed essential to find out as far as possible what the soldier in the tropics actually eats, and the Tables II and III, appended, give the results of this inquiry at Columbia Barracks, Cuba, with a garrison of about 1,900 men, and embracing the period from July 1 to December 31, 1899.

We will now take up the components under the headings given in the table and see how far they meet our requirements.

MEAT COMPONENTS.

Requirement 1: Excess of Fats.—The uninitiated, in reading over the ration table in A. R. 1253, would say at once that no excess of fats is *mandatory* therein. But existing orders require the issue of salt meat (which means in practice bacon and pork) 3 days in 10. This is undoubtedly excessive for the tropics. Paragraph II, of G. O. 65 of 1898, would seem to put it in the hands of post commanders to correct this, but practically they do not do it. There seems to be a curious uncertainty in the army as to who shall decide whether the soldier shall get one or another of the alternative issues offered him in the ration table. There are thus many alternatives in the meat components given in A. R. 1253, but the choice of them does not seem to lie with the soldier or his captain.

TABLE II.

Savings made by 18 organizations at Columbia Barracks, Cuba, July 1 to December 31, 1899.

SUSTINENCE STORES.

	ISSUED.	SAVED.	PRICE, CT.	AMOUNT OF SAVINGS.
Fresh beef, lbs.	282,435	18,943	13.24	\$1,846 05
Mackerel, lbs.	7,298	...	6.4	
Ham, lbs.	1,690	...	18.	
Bacon, lbs.	71,550	13,640	7½	1,040 05
Salmon (canned), lbs.	2,579	...		
Corned beef (canned), lbs.	6,091	...	13.75	
Fresh fish, lbs.	2,579	...		
Flour, lbs.	398,595	94,562	2.08	1,966 89
Corn meal, lbs.	1.24	
Beans, lbs.	26,238	1,475	8.23	47 64
Peas, lbs.	1,057	...	2.87	
Rice, lbs.	17,256	2,967	3.77	111 86
Hewley, lbs.	2.	
Potatoes, lbs.	199,660	...	8.61	
Onions, lbs.	39,763	...	2.91	
Canned tomatoes, lbs.	43,175	...	2.17	
Coffee, lbs.	35,430	9,220	12.	1,106 40
Sugar, lbs.	53,146	524	8.90	20 41
Dried fruit, lbs.	44,879	...		
Total				\$6,189 33

Average strength of garrison 1,900 men.

It will be observed that the savings per capita per diem amount to only 1½ cents, including the savings of fresh beef, which cannot be expended outside of the commissary.

An examination of the articles in Table II, which compose the great bulk of the soldiers' fare, will show that there is much truth in the remark made by a medical officer in a recent article on the ration¹ that "the variety stated on paper is very delusive." In 185 consecutive days at Columbia Barracks, Cuba, beef was issued 124 days and bacon 47 days. The variety is, in truth, much like that at the boarding-school where there was always a choice of four meats, "Ram, lamb, sheep, or mutton," only in the army it is never mutton. Bacon is issued 3 days in every 10, and the company commander cannot take anything else in its place. He must use it, or sell it, and in the latter case can sell it only to the commissary,² which will give him for it only 7½ cents a pound, less than one-third of the value of the beef-ration. If he sells it there is a loss to the company fund, as compared with the value of the fresh beef-ration, of \$103.23 a month—the strength of the company being 100 men. This is more than the average amount of the monthly savings per company.

There is thus a pecuniary compulsion to eat the bacon, which would not be suspected in the most care-

¹ The U. S. and Foreign rations compared—Charles E. Woodruff, Medical Department, U. S. A., in *Medical Record*, May 20, 1899.

² G. O. 16, Division of Cuba, 1899.

ful perusal of the regulations concerning the ration. And practically it is eaten, as is shown in Table II, only 19% of it being sold. It would seem, then, that to meet Requirement 1 there should not be compulsory issues of bacon or (salt) pork except for field service. The low commutation value of bacon and pork will insure their not being too often drawn.

The restriction of the use of bacon and pork refers, of course, to normal garrison life and the garrison issues. In the field they are indispensable. A certain amount of fat is needed also for frying and other cooking purposes, but this can be purchased in the form of either bacon, pork, or lard, from the commissary out of the savings of the beef ration.

It is recognized that bacon, on account of its keeping qualities, the ease with which it is cooked, and its high value in calories, is a valuable if not indispensable emergency ration, and that a certain amount must be kept on hand in commissaries to meet the exigencies of field-service. Nor will bacon keep indefinitely, and this supply must be, from time to time, renewed. But in these days of telegraphs and fast steamers this supply need not be large, and A.R. 1236 seems to provide a remedy against loss from deterioration, preferable from a hygienic standpoint to forcing it down the throats of soldiers, namely selling it.

Requirement 2 will be met to a large extent by permitting company commanders to make a liberal saving of fresh beef. The restrictions which now surround this privilege rob it of much of its value, the savings being limited to 1 day's issue in 10, and not being paid in cash, but taken out in trade as it were. The price of fresh beef is so high that the temptation to make savings of it would, if these restrictions were removed, insure to a considerable extent against an excessive consumption. But to guard against the well-known conservatism of the company-cook it would be better to issue only the English allowance of 12 ounces of fresh meat, the balance being commuted in cash.

Fresh fish is abundant and cheap in almost all parts of our new tropical possessions, and it is somewhat surprising that the recent authority for the issue of this cheap, excellent, and wholesome variation of the meat ration is not more taken advantage of.

I am informed that the men eat it gladly when issued. Conservatism, which is so characteristic of the military service and, in matters of food, of the Anglo-Saxon race, together with slight administrative difficulties which with practice would disappear, seem to be the causes of its comparatively limited use at Columbia Barracks. It has, however, been more regularly used at other posts in this department.

Routine is dear alike to the commissary-sergeant and company-cook, and these two important persons have more influence than is generally recognized in deciding what shall go into the company kitchen. When the greater trouble and labor to the latter in preparing and cooking fish is considered, as well as the fact that the fish-ration is less than that of meat, the absence of fish from the bill of fare, where its use is optional with company authorities, is largely explained. Being a less satisfying food than beef, and the waste—heads, tails, entrails, etc., being greater than the proportion of bone in beef—being sometimes as much as 35%, no reason is known why the ration should be less than that of beef, viz., 20 ounces.

Fish is largely eaten by all tropical races near the sources of supply and is undoubtedly less stimulating

and more easily digested than butcher's meats. For this cause, and to secure variety, fresh fish, where obtainable, should be issued twice a week, no savings being permitted.

Mutton is authorized in place of beef where the cost does not exceed that of the latter, but in the ration as issued this provision seems to be a dead letter. I have not in 15 years of service known of its issue that number of times, and the contract for Cuba does not, I am informed, make mention of it. In the rare instances when issued it has been at the request of the contractor and for his own convenience.

There is an impression among army cooks that mutton contains more bone and less meat to the ration than beef and so does not go so far. If this were true we could well afford in the tropics to sacrifice some little from our luxur consumption of meat to gain in variety. Mutton being a drier meat than beef stands refrigerating even better and improves, as is well known, by refrigeration. For the sake of variety the Commissary Department should issue it at least 1 day in 10, or better once a week, as in the English service, and the limitation as to relative cost should be removed.

The issue of the meat components at Columbia Barracks, Cuba, for 185 consecutive days has been as follows:

Fresh beef	124 days
Mutton	None
Bacon	47 days
Fresh fish	1 day
Other issues	13 days

Which shows well the monotony of the issue, the only important variant being the undesirable bacon.

A certainly more desirable issue, and one apparently permissible according to the paper-ration, would have been, for example, somewhat as follows:

Fresh beef	100 days
Fresh mutton	37 days
Fresh fish	38 day
Other issues	10 days

A saving of $\frac{2}{3}$ of the fresh meat being authorized.

As fresh fish is quite cheap at Havana the difference in cost would have been immaterial.

VEGETABLE COMPONENTS.

The same failure to provide the greatest variety possible under the regulations which we observed in the meat component is found in a far greater degree when we come to the fresh vegetable supply.

Potatoes and onions are the only fresh vegetables habitually issued to the soldier, and the provision of "4½ ounces of other fresh vegetables, not canned, when they can be obtained in the vicinity of the post or transported in a wholesome condition from a distance," in which one catches the promise of occasional cabbages and beets, turnips and sweet potatoes, squashes and string beans, corn and fresh tomatoes, is practically a dead letter. Of course it is not to be expected that a variety of vegetables can be furnished the soldier in the field; there, if he gets potatoes and onions, he is lucky. But in garrison, with abundant markets near at hand, it is practicable for the post or regimental commissary to make his purchases of fresh vegetables in large variety, and it is not necessary or right that the vegetable issue should be limited to an eternal round of potatoes and onions. It should not be left to the company-fund to provide this variety. An

examination of Table III shows that the company fund is entirely inadequate.

TABLE III.

Amounts of fresh vegetables purchased from company funds of 18 organizations at Columbia Barracks, Cuba, during the period from July 1 to December 31, 1899:

Cabbage	3,464 heads.
Sauerkraut	21 barrels.
Potatoes	225 "
Sweet potatoes	34 "
Turnips	15 "
Beets	11 "

Other fresh vegetables, string beans, pumpkins, lettuce, radishes, squash, fruits, etc., to the value of \$522.75.

The total expenditure was approximately \$2,800, or $\frac{1}{2}$ of a cent per capita per diem.

In addition, canned vegetables in considerable amounts were purchased from the commissary.

The income from the savings is there shown to be only 1 $\frac{1}{10}$ cents a day per capita and of this not quite one-half is spent for fresh vegetables.

If the Subsistence Department will not furnish this variety the company fund should be increased by authorizing a liberal meat-saving and perhaps also by a money commutation for this purpose. But if in the United States it is to be regretted that the issue of fresh vegetables is in practice limited to potatoes and onions; in the tropics, where for seven months in each year a really good potato cannot be had, it is simply folly. The most important members of the vegetable ration, aside from the bread furnishing the main supply of carbohydrates, are rice and potatoes. In the ration rice is an occasional and commutable issue, taking its turn with beans and peas, while the potato is a daily issue, furnishing the great bulk of the fresh vegetable allowance.

Since 1892 I have been continuously stationed, with the exception of one year, in Florida and Cuba, and the conviction has constantly grown upon me that for hot climates these two should in relative importance be reversed. In our own country in traveling south, as soon as one reaches the Cotton States, one finds that the potato, which in New England and the Northwest dominates the table at every meal, has retired to the secondary and humble position of an occasional visitor at dinner, while rice, which was in the North an occasional and glutinous mess, is perfectly cooked and always in evidence. Advancing still further south we find when we reach the tropics that rice becomes the mainstay in the support of whole populations, while the potato has retired into relative insignificance—taking a stand well to the rear of the sweet potato, yam, and banana.

The reasons are not far to seek. The home of the potato is in relatively high latitudes or altitudes, and though it will grow in the tropics, it is there an unhealthy exotic which will not keep, nor will potatoes brought from the United States keep in the Antilles during the spring and summer, during the three weeks or more necessary to get them from the hands of the dealer in New York into the hands of the company-cook in Cuba. In the Philippines this difficulty is, of course, vastly increased. At Key West so heavy was the loss of potatoes shipped from New York by water during the 7 months between March 1 and October 1, and so constant the complaints, that the Commissary Department at length, at the request, I believe, of the contractor, had the potatoes inspected at the dock in New York. These potatoes would spoil so rapidly in the hot hold of the vessel, that though excellent when inspected, when issued to troops at Key West a 10 days' issue would frequently yield only enough for two or three meals.

The loss of starch from these changes will be in those which are not rotten very considerable, a loss which can be but ill afforded by a vegetable which at best contains only 21% of starch. Of course the antiscorbutic value of the vegetable salts, chiefly citrates, in the potato has more than any other quality given it its unique value among the carbohydrate producers of the temperate zone, but this is of small importance in the home of the citrus fruits, and where we have in the sweet potato and banana antiscorbutics of equal value.

As a food, rice contains four times as much proteid and four times as much starch as potato. To get the 600 grams of carbohydrates which are needed with a reduced fat allowance from potatoes alone, it would be necessary to consume 6.25 pounds, costing 16.35 cents, while with rice it would be supplied by 1.73 pounds, costing 7.04 cents. Yet such is the conservatism of the American soldier, and such the obstinacy of the company-cook, that we find companies selling part of their rice and buying more potatoes to make up the loss from decay.

It is to be borne in mind, however, that rice is a dry vegetable, and although the allowance of it should be increased in the tropics, it should not be at the expense of the pound of fresh vegetables. That should be issued in full and in vegetables which are really fresh and good, and in all possible variety. Fresh vegetables can be had in all tropical countries, and it is a mistake to attempt to supply them from a distance of from 1,000 to 8,000 miles. Instead of being limited to potatoes therefore, the fresh vegetable components should be of fresh vegetables in all possible variety.

The following is a list of the common vegetables, several of which can be obtained in abundance in Cuba at almost any season of the year, while during the winter most of them are abundant, and, with proper care to get competitive prices, reasonably cheap:

Sweet potato,
White potato (in winter),
Cabbage,
Onions,
Kershaw (pumpkin squash),
Beets,
Turnips,
Yams,
Plantains,
Bananas.

The value of the native sweet potato as a substitute in the tropics for the exotic white potato has been so far curiously overlooked. It is always to be had and is always good.

The vegetable components of the tropical ration should then be:

Dried vegetables: Rice, 2 $\frac{1}{2}$ oz.; frijoles, 2 $\frac{1}{2}$ oz.; or macaroni, 2 oz.; fresh vegetables in proper variety, 16 oz. (Purchased, if practicable, in the vicinity of the post or command.)

Rice, it should be observed, is a daily, not an alternative, issue.

Dried fruits are a recent and most valuable addition to the ration. In the field when fresh vegetables cannot be supplied, canned tomatoes and other canned vegetables may be issued in lieu of them, or a money-commutation of 5 cents should be paid in lieu of the fresh vegetable component, so as to permit of company or individual purchases. The commanding officer should be authorized in the field to increase the dried-fruit component to 3 ounces when deemed necessary.

The changes proposed are not radical or expensive,

yet they will make the dietary conform alike to the rules of physiology and experience, and they cannot but have a vast influence for good on the health of the soldier. The great perils of the tropics, aside from infectious diseases, come from disorders of the digestive apparatus, and even the infectious diseases cannot be wholly excluded, as it is well known that intestinal disorders quickly break down the resistant force of the organism and render it an easy prey to infections. Diseases of the digestive organs constituted at Columbia Barracks 44% of all admissions for diseases during the last 6 months of the past year. If the various infections,—malarial, typhoid, etc.,—which find in the subjects of gastrointestinal disease conditions favorable to invasion of the system, could be added to these, the sum would be, I believe, a surprisingly large proportion of all cases of disease.

If, in the tropics, alimentation is in truth the foundation of the temple of hygiene, and if the health and efficiency of an army will depend upon its rations, it is clear that the Sanitary Corps must have a voice in the selection of that ration, and considerations of convenience of supply and relative cost, which have so far been of controlling importance, must be weighed against hygienic considerations with which our efficient subsistence department is of course unfamiliar.

Hence the necessity for a mixed jury and a scientific and unbiased verdict.

PRINCIPLES OF ASEPSIS APPLIED TO OPERATIVE AND OTHER WOUNDS OF THE EYE.¹

By EDWARD JACKSON, A.M., M.D.,
of Denver, Col.

[Concluded from page 1092.]

On this account hemorrhage, and particularly long and general capillary oozing, is to be favored. And while blood-clot should be so watched and removed as to prevent its serving for a nidus for germ development, it must be properly respected as a normal bar to infection. Its disintegration and washing away by watery solutions must, at times, prove harmful. The power of cocaine to prevent hemorrhage is a two-edged weapon that may readily be pressed so far as to do harm by aiding infection that will more than balance the increased ease of operating without hemorrhage. The yet more powerful styptic, adrenal extract, must also be watched lest it prove harmful in this same way. I believe that deficient hemorrhage is an important factor in permitting the infection of the eyeball by penetrating wounds, with or without the lodgment of a foreign body; and that I have done good by operative interference when it accomplished little more than the production of free hemorrhage into the tract of injured tissue.

The failure of hemorrhage to accomplish the removal of all foreign matter, and complete the disinfection of a wound, causes the need for drainage. This is the same process prolonged and more or less modified. If not interfered with, it may in the end be entirely effectual. The older surgeons, whose early cleansing of wounds was less efficient, were compelled to recognize the importance of free drainage. It is too often forgotten in the ophthalmic surgery of today. In the following instances I am sure more general importance should be attached to it.

There has grown up in the profession a feeling that it is somewhat dangerous to enucleate an eye during panophthalmitis, on account of liability to subsequent meningitis and death. Statistics of large numbers of cases indicate that the risk must be comparatively slight, while reported cases show that the fatal meningitis may arise when the eyeball has not been enucleated. Probably whatever risk may have attended enucleation in these cases has been due to the common practice of subsequently packing the orbit with sponge, lint, or absorbent cotton-pads to check hemorrhage, and then leaving these in position, under a pressure-bandage, for 12 or 24 hours, or even longer. That this practice has not been more frequently attended with disastrous results seems to prove the efficiency of the natural processes for wound-cleansing, and the value of the resistance of living tissues to infection. In many of these cases, a proper grasp of sound, surgical principles regarding sepsis will lead to encouraging the hemorrhage rather than attempting to cut it short, and when it ought to be checked, this can be done so quickly and cleanly with hot water, that I never have seen any excuse for packing the orbit.

The wounds which give rise to sympathetic ophthalmia are wounds penetrating the nonvascular media of the eye, and so not likely to be thoroughly cleansed by hemorrhage. They are also liable to be but imperfectly drained on account of the early closure of the wound in the ocular coats. Then, as has been pointed out by Randolph (*New York Medical Journal*, February 23, 1895), the wounds of the ciliary region, long known as especially dangerous in this connection, are particularly likely to have drainage prevented by closure by swollen lens matter, or by the entanglement of parts of the ciliary processes. The enlargement of such wounds and the careful removal of all obstructions to free drainage will surely come to be recognized as an important duty of the surgeon who undertakes their care.

Probably the most important legacy left to us by the writer on ophthalmology, Van Millingen, who recently died at Constantinople, was his history of 3 cases (*Centralblatt für praktische Augenheilkunde*, June, 1899) in which he plunged the galvanocautery into the depths of infected wounds of the eyeball that had been doing badly, and thus brought about their early and satisfactory healing. The full appreciation of the importance of thorough cleansing will certainly lead to more general and more radical interference in cases of penetrating wounds of the eyeball. Up to the present time the history of the great majority of cases of "successful" extraction of bits of iron from the vitreous chamber, with the electro-magnet, has ended in at least the functional loss of the eye. This seems the natural result where the foreign body is removed without any attempt to take with it, or to disinfect, all infected tissue. In the two cases of magnet extraction from the vitreous in which I have secured the permanent retention of good vision, both the foreign body and all tissue immediately surrounding it were removed through openings large enough to ensure free drainage. We probably have much to learn about how it is best to interfere in injuries of this kind, but that there must be intelligent and thorough surgical intervention to secure the complete cleanliness of all deep wounds of the eyeball seems certain. The requirements of modern aseptic surgery cannot otherwise be complied with.

¹ Presented at the meeting of the Rocky Mountain Interstate Medical Association, Butte, Montana, August 28, 1900.

In his recent Alvarenza prize essay on Regeneration of the Crystalline Lens, R. L. Randolph, in discussing the frequency of infection in the eyes of animals experimented on, because of the impossibility of such after-treatment as can be given the human eye, uses these words: "Let me say again that neatness and accuracy of technic at the operation will go a long way towards compensating for the lack of after-treatment." This is not the utterance of an old-school operator, but of a skilled bacteriologist. It sets forth a truth formerly better appreciated than it is now; but which has not been at all superseded by the discoveries of the laboratory or the routine of the antiseptic operating theater. Simplicity and good judgment in the planning of an operation, and neatness, accuracy, and rapidity in its execution are absolutely essential to the ideal asepsis. No routine of chemical antiseptics can compensate for torn, bruised, or otherwise injured tissue in the lips of an operative wound. In cataract extraction it is probable that the highest success is missed more frequently through working with a dull knife, or one of unsuitable shape, or through applying force to it in the wrong direction, than through having it imperfectly "sterilized." It needs to be more generally taught and remembered, that no routine can make bungling surgery aseptic.

Briefly to recapitulate: There is danger that these principles may be lost sight of in the common routine of operations and wound treatment.

External antiseptics cannot replace the natural barriers to infection, and must not be suffered to impair them.

Hemorrhage is of great importance in securing asepsis, and its management should be undertaken with this purpose well in view.

Free drainage is still essential for most penetrating wounds of the eye; and the complete cleansing of ocular wounds should be secured, if possible, even at the cost of considerable operative interference.

Perfect mechanical results, to be secured by perfect operative technic, are essential to perfect asepsis.

THE X-RAYS IN THE TREATMENT OF CARCINOMA.

By WALLACE JOHNSON, M.D.,

of Washington, D. C.,

Demonstrator of Pathology, Georgetown University Medical School, and in Charge of the Pathological Department of the Lione Laboratory at the Central Dispensary and Emergency Hospital,

AND

WALTER H. MERRILL, B.L.,

of Washington, D. C.,

In Charge of the X-Ray and Photographic Department of the Lione Laboratory at the Central Dispensary and Emergency Hospital, Washington, D. C.

[Concluded from page 1091.]

CASE 3—B. C., an Irish stonecutter, aged 60, poorly developed and poorly nourished. Some time in the latter part of the summer of 1899, he noticed a small abrasion about the middle of the lower lip at the junction of the skin and mucous membrane. This became painful and spread steadily until the patient applied for treatment February 21, 1900.

The original condition was as follows: "At the middle of edge of the lower lip is a small tumor, almost spherical in shape, 2.5 cm. in diameter, extending about equally over the mucous and skin surfaces. Where the surface is not covered with a crust, it discharges a bloody, foul-smelling serum. The patient complains of constant pain in the diseased part."

A small piece removed for microscopic examination proved it to be epithelioma, as is shown by the accompanying photomicrographs. (See plates Nos. 4 and 5)

Treatment was instituted at once. The growth was ex-

posed to the action of the focus tube on every second day for 4 exposures. There followed an intermission of 18 days to determine the severity of the dermatitis produced. March 20 treatment was renewed and three additional exposures were given.

FIG. 4.—From a section of specimen of Case 3.—Leitz obj. No. 3; oc. No. 4.

The results noted are, first a disappearance of pain in the lip which followed the first treatment and remained permanent; second, the quantity of the discharge was lessened and the discharge itself lost its offensive character; third, very little dermatitis was produced and the tumor did not diminish in size. The patient did not return for treatment after March 23. Improvement in this case consisted in the relief from pain and from the offensive discharge.

FIG. 5.—Same as Plate IV with higher magnification.—Leitz obj. No. 7; oc. No. 1.

CASE 4.—Mrs. S., aged 33, has a good family history and has always been well and strong until the present trouble commenced. After her third child had been weaned she noticed a tumor in the right breast which rapidly increased in size. Her physician advised removal and excised the entire breast in the early part of the year 1899. A few months later the tumor returned and a second operation was necessary. This also was unsuccessful. Removal by paste was then undertaken, and these applications continued until the patient came to us in April, 1900.

The following observations were then made: "The patient is weak and anemic, has no appetite, and complains

of much pain in and about the scar of the first operation. This extends from the axilla to the sternum, which, with the surrounding skin, is bound tightly down to the ribs beneath. Above this scar at the axillary end there is a small nodule which may be due either to a diseased gland or to the puckering of the tissue in the contraction to form the scar. This had escaped the patient's notice and was not observed until we called her attention to it. A little

FIG. 6.

internal to the mammary line above the scar is a tumor, about 5 cm. in diameter. This mass, like the scar-tissue, is tightly bound to the ribs, and while not painful to the touch is a center from which at intervals shooting pains radiate. This tumor has sharp, well-defined margins. Below the scar, on the sternum, is an open ulcer from which a tumor is said to have been removed by paste only a week previous. This application had been made 3 times here without effecting a cure. There is, however, a scar slightly external to this place, from which a tumor is said to have been successfully removed by this process."

Treatment began over this open place first, then over the large subcutaneous tumor, and lastly over the nodule at the anterior border of the axilla. The time during which the patient has been under treatment extended from April 9 to the time of writing, May 21.

During this interval the patient has experienced absolute relief from pain, has increased in weight and has improved in general appearance. The open discharging ulcer has been changed to a cicatrix, over the center of which a dry scab one centimeter in diameter has remained for twelve days. The original opening was 4 cm. in diameter. The margin of the large tumor has softened, and its diameter has reduced one centimeter. The tumor also seems to be less prominent. No change has yet been observed in the nodule owing to the shortness of the time it has been under treatment. The entire relief from pain and the generally improved condition of the patient would seem to justify the treatment, though the report at this time is necessarily incomplete. Treatment will continue for the present.

CASE 5. — Mr. P. C., aged 72 years. Has always enjoyed good health. Family history good. No syphilitic,

tuberculous or cancerous taint. He says his present trouble dates from a razor cut, of the external nasal septum, inflicted several years ago. This would not heal, for he kept continually scratching and rubbing it, on account of its intense itching. His nose before the onset of the disease was thin, sharp and straight, but it has gradually taken on the bulbous, knot-like appearance, shown in the accompanying photograph (Fig. 6.) The septum is now very much broadened and thickened. Clots of blood form within the nose. Inspection shows a few very small raw surfaces on the anterior internal surface very near the margin of the external opening. The external surface of nose appears slightly reddened and presents five ulcerating surfaces, which are only slightly depressed. They discharge a considerable quantity of purulent serum having a disagreeable odor. A section taken from the nose for microscopic examination proved it to be a typical epithelioma. Patient complains of great itching in nose.

Treatment began at once, July 1, 1900, with an exposure of the whole end of the nose for seven minutes to the most intense burning ray we could produce. Although a decided dermatitis appeared by the end of the week, treatments of twenty minutes each were given on July 7, 9, 12 and 16. The whole surface exposed soon developed into one large discharging ulcer which did not commence to granulate over for three weeks. By the end of August the nose had become entirely covered over by new skin and very much diminished in size. The second photograph (Fig. 7) was taken November 2, just four months after Fig. 6, and shows an apparently complete return to the normal.

CASE 6. — Mr. M., aged 55, presented himself for treatment August 3, 1900. He had a small superficial ulcer 4 to 5 mm. in diameter on the tip of his nose. This presented a slightly depressed, easily bleeding surface from which exuded a small amount of serum. He said that for two years this had been treated by dermatologists and others without any beneficial result. In fact the place became progressively larger and worse. It never discharged more than enough to keep it covered with scales, or later a scab. A portion for microscopic examination was not obtainable,

FIG. 7.

but the symptoms, history and appearance all warrant the diagnosis of epithelioma.

Treatment was commenced August 3, with an exposure of seven minutes. This was followed by seven minute exposures on each of the following dates, August 8, 11, and 13. The part of the nose treated reacted promptly, but the inflammation produced was not severe enough to cause profuse discharge or slough. The surface promptly healed

over and two weeks later no remnant of the disease was apparent. There has been no sign of recurrence up to the present time, November 23, 1900.

APPARATUS.—The apparatus needed for the work is that used to produce the x-rays; it should be borne in mind, however, as the object is to set up a dermatitis, the so-called x-ray burn, the static machine and smaller coils are not applicable. Experiments have shown that next in importance to the exciting apparatus comes the kind of tube used to give rise to this dermatitis. Professor Röntgen in one of his papers alluded to the difference in the nature of the x-rays produced by the "soft" or low vacuum tube, and the "hard" or high vacuum tube. The former takes a greater quantity of current, heats more quickly and emits x-rays which do not penetrate objects as readily as those from the latter. Yet these rays have a more intense action on a photographic plate. They spend their energy on the first object they meet. Operators have found that these "soft" tubes are most likely to produce that peculiar series of local symptoms called variously the "x-ray burn," "white gangrene," "focus tube dermatitis," etc.

For our purpose, then, we select a soft tube, but before using it on a patient its burning time is determined. This is very important, for we have found that of two equally soft tubes operated on the same current, one may produce a burn in 3 minutes, while with the other an exposure of 30 minutes may be necessary to effect the same result.

We expose to this action not only the area evidently diseased, but also surrounding tissue for a little distance. The healthy skin beyond is protected by tinfoil of moderate thickness. It is our object to produce a mild inflammation and pigmentation in and about the diseased tissue, gradually increasing its severity until we have a burn of such depth that it will require 6 weeks to heal on the normal skin. The treatment is then suspended for a month and if a complete cure is not in prospect at the end of this time, the process is continued over those parts which still resist.

At the time of exposure the patient experiences no uncomfortable sense of heat; in fact, there are no sensations whatever. The time required for the treatment is not burdensome in view of the palliative results which occur almost immediately, and the permanent benefit obtained in a few weeks. The photographs of Case 2 were taken only 6 weeks apart. The relief from pain followed the first treatment in three cases; this is really surprising when one considers the persistent character of the pain in these cancerous growths. Cases 1 and 3 show far better cosmetic results than could have followed radical surgical interference, and subsequent plastic surgery has a smaller defect to remedy.

We fully realize that the number of our cases is far too small for any generalization, and yet they lead us to hope that when others report cases similarly treated and when our own list is longer, the medical profession will be ready to admit that the x-rays are a valuable addition to the therapy of this dread disease.

Treatment of Plague.—The annual report of the Secretary of the Agricultural Department states that the work of preparing serum for treating hog cholera and swine plague and experiments in treatment with it are continued. The results do not justify definite conclusions, but are encouraging enough to warrant further experiments, some of which will be on entirely new lines.

SOME REMARKS ON THE HYGIENE OF THE EAR.*

By EMIL AMBERG, M.D.,

of Detroit, Mich.

As knowledge of diseases of the ear increases, the importance of prophylactic measures in this branch of medicine is better understood. This paper deals with the hygiene of the ear: First, in connection with the proper care of the nose and throat; second, with general diseases; and, third, in general daily life.

The close connection of the nose and the throat with the ear through the eustachian tube, which, especially in children, forms a comparatively short and wide communication between the nasopharynx and the middle ear, readily explains why diseases of the first affect the latter. These affections are brought about in two ways. A certain amount of air must constantly be in the tympanic cavity, and all of us are acquainted with the consequences of an abnormally diminished air-supply. As the air is absorbed it must be renewed. The constancy of the air-supply is guaranteed by a permeable eustachian tube; therefore one can readily understand why, for example, adenoid growths may cause changes in the middle ear, which permit us to speak of an adenoid ear. Again and again, this fact has been brought to the attention of the general practitioners, of educators, of the laity, and, in spite of all, it seems to be neglected. Whenever we see a child breathing with open mouth, and we learn that it snores at night, if it has a characteristic nasal pronunciation, sometimes also a stupid expression, we should always examine for adenoids, and, when they are found, we should remove them. There scarcely seems to be a more satisfactory operation at our disposal, and the advisability of examination for adenoids should be suggested to parents. Whenever the proper ventilation of the nose and of the nasopharynx is interfered with, secondary pathologic changes may easily take place and the middle ear may be infected through the eustachian tube or if pathologic material is blown into the ear. Adenoid children frequently suffer from nasal catarrh. In cleaning the nose, as a rule both nostrils are closed, and it is not surprising that, in this way, microbes are thrown into the middle ear, where they find a favorable soil to grow. A case in point came under my care July 5, 1900:

Mr. E. M., aged 20 years, says that he never had trouble with his ears until last January. At that time he blew his nose in the usual improper way, and felt immediately "as if the left side of the head was plugged up." About one week later he noticed a discharge from the left ear. Last April he used some salt water as snuff, closed both nostrils and, as he expressed himself, accidentally "washed a little in the other (right) ear." Since that time he has had continuously a "funny" feeling, as he says, in the right ear. Upon examination: Right ear, drum membrane injected in upper half, especially in posterior part, somewhat bulging, no pain. Left ear, perforation in anterior lower quadrant, ear apparently dry. Hearing diminished in both ears for voice and watch. Weber on right. Spur of nasal septum on left. General health not good the past year, and still under treatment for pulmonary trouble.

If we further consider that sometimes, in order to influence a nasal catarrh, the proper source of which is not found, a nasal syringe is used instead of instruments like Fraenkel's or Bermingham's nasal douche, it does not surprise us that harm is done when good is

* Read before the Section on Surgery and Ophthalmology, at the annual meeting of the Michigan State Medical Society, held at Mackinac Island, July, 1900.

intended. Especially in children the nasal syringe should be abandoned, on account of the short and wide eustachian tube.

Professor Guye¹ (Amsterdam) comes to the conclusion: "First, no syringing should take place in the nose, but only instillations should be employed, unless the physician has proved to satisfaction the permeability of the nose. In the first years of life, the nasal cavity should not be syringed at all. Second, if the nasal cavity should be syringed, there never should be used a tip which closes up the entrance to the nose." A. Bruckmann² tells of a number of cases compiled from the literature, in which the nasal syringe caused disease in the ear. Bacteriologic examinations by Netter and Zaufal⁴ showed that in most cases of otitis media after irrigation of the nasal cavity *Diplococcus pneumoniae* Fraenkel-Weichselbaum and *Streptococcus pyogenes* have been found in the tympanic cavity. Muehr recommends care in irrigating the nose.

If a syringe must be used, Schwartze's instrument is preferable, because it works from the nasopharynx towards the front. Concerning the treatment of adenoids as a prophylactic measure for disease of the ear, nothing short of removal of the growths at the earliest opportunity can be recommended. Haug reports that in 347 of 410 cases adenoids were the cause of diseases of the ear.

Enlarged tonsils do not require less attention, and also every affection of the nose and nasopharynx which interferes with the proper circulation of air. Ad. Barth⁴ says: "On account of some observations I am compelled to think that under circumstances a simple prevention of free breathing through the nose may give rise to an acute or chronic suppuration in the middle ear."

Fink,⁵ in his valuable essay, quotes Wurtz and Ler-moyer, who showed that the normal secretion of the nasal mucous membrane destroys microbes. Only the normal secretion, however, acts in this way. Fink speaks of the evil effects of coryza in infants, which shows itself in affecting proper nutrition, sound sleep, etc.

Of all affections of the ear, 60% are said to be caused by affections of the nose and the throat, and still the strange combination, oculist and aurist, exists. We know that infection of the ear takes part in general diseases more than is commonly supposed, be it through the eustachian tube or through the circulation, or through centrally located affections. Recently this fact has come more and more to attention by the search in autopsies for pathologic changes in the ear. Although it is a well-known fact that in many acute infectious diseases the ear is not exempted, as in diphtheria, scarlet fever, measles, influenza, pneumonia, mumps, typhoid fever, etc., it remained for a more recent date to show in what an unexpectedly large percentage of cases the ear is involved.

In this connection, I may add a suggestion in treating an acute suppurative middle ear. Politzer⁵ says that with every acute middle-ear suppuration pus is found in the cells of the mastoid process, because pus flows into the mastoid antrum and cells when the patient lies on his back. This, naturally, does not always lead by necessity to a real inflammation of the mastoid process. According to this statement by Politzer, it might, perhaps, be advisable to consider whether it would not be wise to forbid these patients to lie on the back for a number of days, in order to avoid a mastoid complication.

A very important factor in preventing deafness and deafmutism is the proper consideration of marriages between people who are deaf and in the families of which deafness exists. We have a direct, or an indirect inheritance,⁶ and the result of consanguineous marriages. Direct inheritance is caused if one or both of the parents are deafmutes; indirect inheritance is such that develops deafmutism only in the second or third, or even later, generations. However, deafmutes, or consanguineous parents may have children with entirely normal ears. Alexander Graham Bell,⁷ after a careful study of the question of consanguineous marriages, says: "I do not look upon the consanguineous marriage as a cause of deafness, but as a means of increasing and intensifying the defect where a tendency to deafness already exists. We have no proof that a consanguineous marriage produces deafness in a family which has, hitherto, been free from the defect." He says further:⁸ "1. A deaf person, not born deaf, who has no deaf relatives, will probably not increase his liability to have deaf offspring by marrying a blood relative. 2. A deaf person, born deaf, who has no deaf relatives, will probably increase his liability to have deaf offspring by marrying a blood relative. 3. A deaf person, whether born deaf or not, who has deaf relatives, will probably increase his liability to have deaf offspring by marrying a blood relative, especially if that relative should happen to be on the deaf side of the family. For example: If his father has deaf relatives and his mother has none, he will be more likely to have deaf offspring if he marries a relative of his father than if he marries a relative of his mother." Speaking in general, he says:¹⁰ "As there are few families entirely free from constitutional defects of some kind, a prudent person would do well to avoid a consanguineous marriage in any case, not necessarily on account of deafness, but on account of the danger of weakening the constitution of the offspring. Remoteness of blood is eminently favorable to the production of vigorous offspring, and those deaf persons who have many relatives deaf would greatly diminish their liability to have deaf offspring by marrying persons very remote in blood from themselves. Deafness and other defects would be most likely to disappear from a family by marriage with a person of different nationality. English, Irish, Scotch, German, Scandinavian, and Russian blood seems to mingle beneficially with the Anglo-Saxon American, apparently producing increased vigor in the offspring." As probabilities for guidance for deaf people, in order to diminish the liability to have deaf offspring, Bell gives the following: First, by marrying a hearing persons in whose family there is no deafness. Secondly, by marrying a deaf person (not born deaf) who has no deaf relatives, or a hearing brother or sister of such a person.

Professor Fay¹⁰ divides 5,000 marriages, in which 8,000 deaf persons were concerned, into 2 groups, those concerning people known to have deaf relatives, and those not known to have had such, etc. Deaf persons who have deaf relatives will have nearly 40% of deaf children, while deaf persons without deaf relatives, who marry, will have only 1.2% of deaf children. Brooks comes to the conclusion that "The intermarriage of people with deaf relatives is almost sure to result in deaf children, more than half of the children being deaf, whether the marriage is between deaf or hearing people."

It is important to mention that *lues hereditaria* may

cause deafness, even in more advanced ages. I had 2 cases under my observation which I think to be of this character; other symptoms made the diagnosis very probable. One girl became deaf when about 15½ years old, and another at the age of 10. Frankenberger¹¹ believes that adenoids can cause deafmutism. This can be easily understood if we remember that a child always becomes a deafmute if it is deaf before it is 4 years old, and usually if it is deaf before it is 7 years of age.

As acquired deafness mostly results after meningitis, scarlet fever, diphtheria, typhoid fever, smallpox, etc., we understand the necessity of continuously paying attention to the organ of hearing under these circumstances. If a child that can already speak becomes deaf, it should be induced to speak much and plainly, and it should enjoy, as soon as possible, instructions for deafmutes. We know that the German method (reading from the lips and use of the sound language) is the most advisable. This also should be learned by persons who are only hard of hearing and not entirely deaf. Jacobson recommends it; I do the same, but I find that my advice cannot be followed in Detroit at present, as I wish it could, on account of the lack of teaching facilities. It seems, however, that this condition will be remedied very soon.

Knowing the connection of the nose and throat with the ear, we should avoid anything which may affect the former. It, therefore, is of great importance that we breathe pure air. We all know that there exists more nose and throat trouble at those times of the year when the wind and the vehicles whirl up the dust on the street. This is a very well-known fact, but little attention is paid to it. Considering that the average number of respirations in an adult is 16 in a minute, 960 an hour, and 7,680 in 8 hours, it certainly must make a difference to the nose and throat, and to the general system, what kind of material we inhale. Whoever keeps his eyes open must be astonished at the lack of understanding and the lack of care which is exercised to avoid the whirling of particles called dust. Nearly every hour of the day the most simple precautions are neglected. Dry dusting and dry sweeping in the houses and on the streets should be avoided. As much as possible the streets should be properly cleansed before people go to their places of occupation. They should be kept free of dust as much as possible, and this should also be considered in public meeting places. I am of the opinion that carpets and draperies should not be used in places where many people meet. That little respect exists for dust can clearly be seen when we remember that travelers in parlor cars even pay the attendant for whirling up the dust from their clothes and hats, so that they and their companions get the full benefit of the same. I think that the dust and the smoke in Chicago have not little to do with the bad prognosis in pneumonia.

At Atlantic City, during the meeting of the American Medical Association, we could enjoy pure air in one part of the city, and only about 100 yards from the boardwalk, vehicles raised an amount of dust which could not have been worse in any place. If the dust contains microbes they can do their work; if it does not contain them, it prepares the soil for them. The evil effects of dust in various occupations have been recognized, and one of the most important hygienic propositions of today is to procure, under all circumstances, pure air.

Winckler¹² says, quoting an experience of Wegman:

"In a woodturner's shop a woman suffering from tuberculosis of the lungs occupied a certain separate place. After she died, a robust and healthy looking girl was engaged. Soon she acquired tuberculosis and died. Another successor experienced the same ill fate. The place got a bad repute on account of the dangerous wood-dust. After close observation, however, it was found that the first tuberculous patient had constantly expectorated on the chippings, and that these had been left in their place for a time until they were removed, at long intervals; that the sputum dried out and got into the air; in this way the successor found a working place strongly impregnated with tuberculosis bacilli. She did not do better than her predecessor, and this gave cause for further infection. There does not exist any doubt that the susceptibility of the entirely healthy organism for the infection for the *Bacillus tuberculosis* can be prepared by the dust. This infection may be more or less slight, respectively, may occur after a shorter or longer time-limit."

Dr. B. R. Shurly, of Detroit, in a paper before a local medical society, reported the very important observation that he found a considerably larger percentage of diphtheria among children who lived on unpaved streets.

An equal temperature is also most important. It has been said that we catch heat as much as we catch cold. We also should avoid the possibility of cold air being blown into the meatus on very cold days, such as we have in Michigan; especially people with wide ear-canals should be careful. I would recommend wearing a little cotton in the meatus in those days. People with perforated drum-membranes must not allow water to enter the ear, not only to prevent an inflammation of the tympanum, but also to avoid the possibility of water entering the lungs in this way. The opinion has been expressed that sudden death while bathing might sometimes be attributed not so much to heart-failure as to the before-mentioned cause.

Unwelcome conditions may follow the piercing of the lobules of the ear. The late Max Thorner,¹³ in an interesting paper on the subject, tells of the bad results—sometimes even fatal—which may follow this "barbaric" custom.

Attention should be directed to the abuse of drugs, especially of quinin, by the public, and sometimes by the physician. Guder¹⁴ made experiments which proved, among other things, that, first, 1 gram of quinin hydrochlorate diminishes considerably the hearing for the watch, and sometimes for the voice, after a time of 2 to 2½ hours. Second: That in 11 cases out of 12, noises appeared after 1½ hours, and that these noises lasted until the next morning in cases which remained long enough under observation. Incidentally, Guder remarks that quinin, if given on account of fever, might best be given 2 to 2½ hours before an attack is expected. Schwabach¹⁵ concluded from clinical observations that permanent disturbances in the ear may take place even after moderate doses of quinin and salicylic acid. It is a custom whenever there seems to be a slight disturbance, to "break up the cold" by taking quinin. I know of a lady who took quinin right along in small doses, as a preventive, without any occasion whatever.

The Fourth of July nuisance must also be considered. I might mention two patients of mine—a lady whose hearing was impaired, not by her own carelessness, on a Fourth of July; the other one, a boy who injured his

ear by firing off about 50 firecrackers. It little astonishes us to hear of those things when we know of the danger to which the ear is exposed with artillerymen, etc.

In regard to the proper care of the system, Haug, in his excellent essay, "Die Grundzüge einer hygienischen Prophylaxe der Ohrenentzündungen," etc., strongly recommends that the teeth should be cleansed and gargles applied in the evening before retiring, and that this should be done after each meal. Further, he recommends rinsing the mouth before each meal. Haug says (page 9): "I can quote from my experience the instance that in some families tonsillitis, diphtheria, etc., which had been endemic in the same, stopped entirely since they followed my orders, without any other help" (removal from infected rooms, operation, etc.). The proper way of gargling consists (Haug) in allowing a small amount of fluid to move slowly backwards, the head being kept in a half-reclined position, and to throw the fluid out after the muscles of the throat contract by reflex. Also a gymnastic of the lungs is advised; 6 to 12 deep inspirations should be made, the mouth kept closed during that time, and this should be repeated in bed 6 to 12 times, not oftener, in a horizontal position. Haug reports that this procedure also helps to procure a sound sleep.

The public, in general, becomes aware of the value of the organ of hearing only after it is impaired. We physicians, guided by our experiences, should carefully steer the public through the straits of life and again and again point out to them where danger threatens.

CHRONIC VILLOUS ARTHRITIS.¹

By S. L. WEST, M.D.,

of Philadelphia.

It is with some diffidence that I assume to direct attention, in particular, to a disease called chronic villous arthritis, in differentiation to the various forms, in general, of arthritis, especially that of the knee-joint. I have selected the knee-joint because it is the largest joint of the body, and the one most exposed to trauma.

Our modern textbooks are conspicuous for their brevity and silence respecting chronic villous arthritis, preferring to class it under chronic arthritis, rheumatoid arthritis and arthritis deformans; but both clinical

and pathologic experience have much to offer in its support. To Schüller belongs the honor of first having clinically and pathologically defined chronic villous arthritis, and thereby clearly differentiated it from chronic arthritis, arthritis deformans and rheumatoid arthritis. Chronic villous arthritis is a peculiar morbid process occurring with relative frequency in young adult life, rarely after the fortieth year, involving generally several joints at the same time. Family history is negative, traumatism may play a far greater part in its production than has so far been demonstrated. Unlike chronic arthritis it does not follow, or depend upon a strumous or poor systemic condition of the general constitution. The progress of the disease, as its name implies, is slow, (chronic) attended with pain, enlargement of the joint structures, impaired motion and usefulness of the joint, and seldom attended with elevation of temperature, except at occasional periods of exacerbations in its progressive activity.

This peculiar morbid process is principally confined to the villi of the synovial membrane, resulting in a chronic hyperplasia of the villi, seldom or never involving the ligaments, cartilages nor bones at their articular extremities. This villous hyperplasia occurs in irregular prominences, in various parts of the articular capsule, thereby differing from both the *acute* and *chronic* forms of arthritis attended with effusion of liquids into the articular capsule; although in some stages of the disease you may have effusion of fluids into the articular capsule; this is, however, subordinate to the villous hyperplasia of the synovial membrane. This hyperplasia is productive of a peculiar fringe-like growth of the villi, much larger than that produced in other forms of arthritis. At the seat of these local prominences, the villi are enormously enlarged. They are generally firm, though under certain not well-defined conditions they become soft and slippery to the sense of touch, indicative of degenerative action. In a freshly opened joint they appear reddish or bluish-red in color and highly vascular. Though this peculiar morbid process may continue for months, or even years, in no instance, so far as I have been able to observe, does it result in destruction of the ligaments, cartilages or bones of the articular extremities. This is one of its strongest points of differentiation from chronic or other forms of arthritis.

As to the etiology of the disease, but little is known or recorded; the weight of clinical and pathologic evidence, however, is in favor of a short bacilli, with polar or dumbbell-shaped enlargement. The inflammatory hyperplasia of the synovial membrane, and enormous production of the villi, as I have above pointed out, as well as the cellular multiplication, are attributed to the action of this bacilli.

The differentiation of chronic villous arthritis from other forms of arthritis will be all the better understood by the following enumeration and classification of such symptoms under their respective forms, as would tend to confound one form of arthritis with that of another, at the same time leaving out of the question the enumeration of those symptoms that are common to all forms which, when taken together, go to make up each form respectively.

In chronic villous arthritis the family history is usually negative; it usually occurs in adult life—rarely after 40 years; trauma may be a causative factor, especially in the monarticular variety; it does not depend upon a strumous diathesis or general poor

¹ Read before the Medical Association of the State of Delaware at its annual meeting at Rehoboth, June 12, 1900.

health; it is attended with pain, enlargement of joint-structure, limited motion, and impaired usefulness; there may be joint-deformity; no elevation of temperature, except occasional periods of exacerbation of progressive activity; it does not materially involve the ligaments, cartilages, nor bones; there is no abnormal heat, nor discoloration of the parts involved; there is seldom effusion of fluids into the articular capsule.

In chronic arthritis the family history is negative; it attacks all ages of youth and adult life; largely depends upon poor systemic condition; there is usually a history of previous attack of acute arthritis or arthritis deformans, or of infectious diseases, as measles, scarlet fever, diphtheria, erysipelas, typhoid and typhus fevers, pyemia, septicemia, pneumonia, malaria, cerebrospinal meningitis, gonorrhea, syphilis, etc.; pain and swelling, with symmetrical contour of the affected joint, limited motion, elevation of temperature, may exist; there is serous (or so-called pus) effusion into the articular capsule, with floating patella; palpation elicits fluctuation; discoloration varying from pink to purple; deformity and enlargement of articular extremities of the bones, ligamentous, cartilaginous and bony degeneration.

In tuberculous arthritis there is family history of heredity; it occurs in early childhood principally; trauma is an exciting cause; there is pain, swelling, limited motion, always elevation of temperature, irregular contour of area affected in early stage—later, symmetrical; effusion of fluids and so-called pus; ligamentous, cartilaginous and bony degeneration; epiphyseal enlargement—usually monarticular, may be polyarticular; the tissue involved may be ivory-colored or colorless in early stage, but in the advanced stage it becomes pink.

Syphilitic arthritis is usually polyarticular, of secondary stage, with a history of primary infection, skin eruption, sore throat, iritis, arthralgia of the joint, redness and swelling, and symmetrical contour; in the tertiary stage there may be gumma in the periosynovial tissues, hyperplastic synovitis, cartilage degeneration; in the hereditary stage, both serous and hyperplastic synovitis with papillary growths, thickened articular capsule and cartilage; periostitis; osteochondritis, osteitis, osteomyelitis of the long bones.

Rheumatoid and gouty arthritis may be monarticular or polyarticular, with history of previous attacks; rheumatic and gouty diathesis, synovitis attended with profuse serous infusion; inflammatory proliferation; chronic thickening of articular capsule and cartilages; enlarged epiphysis with connective-tissue formation; peculiar grating sound caused by the deposition of lime salts in the joint.

In arthritis deformans there may be heredity in some cases; trauma, especially in monarticular form; it may occur at any period of life; acute or chronic hyperplastic proliferation and thickening of synovial membrane may exist; hypertrophy of fringe or villi, filling joint cavity, at times depositing fat in the villi producing a condition known as "arborescent" lipoma; thickening of joint capsule; degeneration of ligaments, cartilages and bones; distortion of joint.

From the foregoing history of this disease the line of treatment suggested is palliative and radical, or medical and surgical. Of the former, rest, regulation of the bowels and general secretory and excretory functions, and appropriate treatment to meet complications. Locally, ichthyol, mercury and belladonna, followed by plaster-of-paris, or silicate of soda dressing to immobilize the joint, give the best measure of benefit. And, of the

latter, free opening up of the joint, under thorough asepsis, excision or removal of the villous hyperplasia, washing out capsular cavity with a 1:1000 mercuric chlorid solution, at a temperature at not less than 110°, close wound by interrupted or other approved suture, apply wet bichlorid dressing, and follow by plaster-of-paris dressing to immobilize the joint. If the villi give evidence of degeneration, after its excision and thorough washing out of capsular cavity with hot bichlorid solution 1:1000, it may be well to inject capsular cavity with warm sterilized iodoform emulsion, put in drainage-tube, close wound with two or more sutures close up to drainage-tube, apply wet bichlorid dressing and follow by plaster-of-paris dressing. At the expiration of a week or ten days follow by second injection of warm sterilized iodoform emulsion, and dress as before. Should impaired motion or false ankylosis of the joint follow, massage and passive motion instituted every second or third day will complete the restoration of the joint-function.

SOME REMARKS ON CATALEPSY. WITH NOTES OF A CASE.

By GEORGE WILLIAM NORRIS, A.B., M.D.

Resident Physician at the Pennsylvania Hospital for the Insane.

THE cataleptic state (by which we understand a neurosis characterized by the patient's inability to change the position of his limbs, while another person can place the muscles in any degree of flexion or extension at will), although by no means a great rarity in our asylums, is perhaps of sufficient infrequency in general practice to warrant a few remarks, and the recital of some notes of a case recently seen at the Pennsylvania Hospital for the Insane.

CASE.—L. L., male, aged 23, a student by occupation, having no history of insane relations, intemperance, nor syphilis, was admitted in August, 1898. In the spring of that year he had been a student at the High School, where, though industrious, he had failed in his examinations, and had in consequence become very despondent.

He continued to worry, ate poorly, lost considerably in bodily weight, and was soon after this time noticed pounding his head against the wall. Six months later (about the time of his admission) he became violent and destructive, requiring to be restrained. He refused to dress or undress or help himself in any way; he was continually soiling his clothes and bedding with his discharges, and had not been heard to speak for a period of 6 months. His limbs offered no resistance to movements and remained in any position in which placed for considerable periods.

Soon after his removal to the hospital he was noticed masturbating, on account of which he was circumcised and bliterated, which seems to have checked the habit.

For nearly 2 years his condition has remained practically unchanged despite treatment, though his physical nutrition has been much improved by the use of good food, tonics, etc. On several occasions he has screamed loudly, and once replied to the attendant, who chided him for not swallowing more quickly, that he "ate as fast as he could." During 22 months he has never lapsed from his cataleptic condition, although varying slightly from day to day in the amount of time in which his limbs would remain in given positions.

The accompanying photographs show well the grotesque positions in which he will remain when so placed. His face meanwhile, void of expression, with upturned eyeballs and a slight quiver of the lids, bespeaking the almost total suspension of intellect and oblivion to his surroundings. He will put forth no voluntary effort, though he does swallow when food is placed in his mouth, and when left to himself gradually leans against some object for support, the chin sinks upon the breast, the arms dangle at the sides, in which attitude when coupled with a pale, clammy skin and scarce

visible respiratory movements, he much resembles a sitting corpse. Indeed death has been simulated by cataleptics to such an extent, it is alleged, that the unfortunate individuals have been buried alive; though at present such an occurrence would be all but impossible.

Showing expressionless face, upturned eyeballs and half-open lids.

On *physical examination* the knee-jerks are found to be much increased. The conjunctival reflex is present, but deep puncture of the skin elicits no response from any part of the integument. The pupils are equal, mobile, and respond promptly to light. An examination of the eye-grounds could not be obtained. The optic axes are slightly divergent. Examination of the heart, lungs, urine was negative. The circulation is sluggish, and the temperature slightly subnormal. Blood count showed 5,000,000 reds and 72% of hemoglob n.

As *etiologic* in the production of this functional neurosis the following conditions have been mentioned: Mental shock, anxiety, grief, and fright. Its chief predisponent is hysteria; hence it is seen most commonly in women during the period of their sexual activity. Of the fact that fright will, in the lower forms of life, produce catalepsy there can be but little doubt. Darwin² has concluded that the so-called shamming of death by insects was nothing more than catalepsy, due to "the paralyzing effects of excessive fear" inasmuch as the positions assumed were not like real death, and hence not brought about by conscious simulation.

This neurosis has also been noted after chloroform and ether narcosis; it is not uncommon in the course of certain mental diseases, notably melancholia, and has been produced in its most extreme degrees by means of hypnotism. Indeed Heidenhein³ remarks that "the hypnotic state is nothing more than an artificially produced catalepsy." It is alleged to have occurred in rare cases of epilepsy; in an imperfect form as the result of malarial intoxication and again in organic brain disease, especially meningitis.⁴ Cases have also been reported as occurring in chorea, pregnancy and anemia.⁵ Vogt,⁶ speaks of an Alpine village near Würzburg, where intermarriage had long been practised, in which one half of the population were subject to cataleptic attacks of a few minutes' duration.

The *duration* of the cataleptic state has in this case been far in excess of the usual time, and while a well authenticated case, seen several times by Charcot, which lasted thirteen years, is on record,⁷ yet attacks enduring from a few minutes to several days are the usual rule.

Niemeyer⁸ regards as closely allied to this condition instances of people who are by emotional shock or great fright "struck dumb," as the saying is, and will remain for several seconds unable to move or speak. And examples of individuals in whom some startling

announcement while eating will cause the momentary arrest of the food-suspending fork before their very mouths, are among the experiences of nearly everyone.

Savage⁹ mentions the case of a cataleptic in whom the so-called "flexibilitas cerea" was so extreme that the patient stood on one leg, holding the arms at right angles to his body for two hours. Instances are occasionally observed in which the rigidity is so great that the individual will remain horizontally extended with his head and heels supported by two chairs, devoid of all intermediary support.¹⁰ Fatigue it would seem having as little place among these cases as in chorea, athetosis and other motor neuroses independent of volition.

As may be regarded from the foregoing, attacks often come on suddenly. Not infrequently ushered in by vertigo, tinnitus aurium, insomnia, chasmus, or a sense of intracranial pressure, the patients remaining rigid in the attitude in which the attack began, and resisting any efforts to place them otherwise. Sooner or later, however, this disappears and is replaced by the almost pathognomonic mouldability [flexibilitas cerea.]

As to the *pathology* of catalepsy, a truly curious perversion of function must exist in order to produce it. A condition which while in a measure allied to spasm, yet produces no resistance to change of position. The motor center, while of sufficient stimulatory intensity to retain the muscles in one poise, accepts with equal

Patient remained in this attitude about 20 minutes, after which arms gradually yielded to the attraction of gravity and sank to his side.

alacrity, and without the slightest opposition, its substitution by another. As summed up by Gowers in an article on the subject: "A deficient control of the motor centers of the cortex, permitting their overaction, regulated by the afferent impulses and repeated in the spinal cord, is the best theory we can at present frame of the process." But it must not be overlooked that a certain proportion of cataleptoid cases develop and per-

sist in this condition owing to the existence of some fixed delusion.

Regarding the frequency of this curious condition, Savage¹ states that "it is rare to be without some cases of partial catalepsy at Bethlehem." Niemeyer¹² remarks that cases of this neurosis belong "*keineswegs zu der Seltenheit*," and I think that most practitioners have usually seen at least one case in their visits to asylums or their attendance to neurological clinics.

The prognosis as regards recovery from the acute attack is usually good, the patient sooner or later passing out of this condition; but in neurotic subjects or through successive attacks, mental impairment often follows. Permanent cure will be likely in proportion to the freedom of the individual from affections of sensibility or motion after the attack.¹³

Recovery may be sudden or gradual; in the former

Patient remained in this attitude about half an hour.

case the patient quickly regaining consciousness; in the latter yawning and stretching like a person aroused from deep slumbers, and remaining in a stuporous and dreamy condition for a variable period. In a case recorded by Rogers,¹⁴ the patient gradually resumed consciousness, being able to write long before he was able to speak, and retaining some recollection of events which had transpired during his attack. As a general rule, however, complete oblivion enshrouds the entire cataleptic period.

In the treatment of catalepsy many drugs have from time to time been recommended and tried, only to be subsequently abandoned. Tonics, alteratives, electricity, massage have been employed with varying success. Rogers¹⁵ cites interestingly two well-marked cases of this disease, which were cured by the continued administration in ascending doses of thyroid extract.

The application of hot and cold douches, the administration of emetics, the inhalation of ammoniacal fumes, amyl nitrite, snuff, etc., have at times served to awaken patients from short attacks. A case of prolonged catalepsy was cured through the continued, alternate application of heat and cold to the head, though the delusions from which the patient suffered before the attack persisted thereafter. Hypnotism has been suggested and tried as a therapeutic measure with apparently as little advantage as in other forms of mental disorder.

In the detection of simulated catalepsy the device first put into application by John Hunter, is at times employed. It consists in attaching to the patient's outstretched arm a weight. Then suddenly, and without his or her knowledge, severing its suspending string; when in such cases the arm will fly upward, while in the true variety it remains stationary, as was the case with our patient.

The treatment in the present instance has been directed mainly toward improving the patient's general condition. Arsenic was administered with negative results, and thyroid extract has been given in increasing doses up to the amount of 60 grains per diem (equivalent to 6 fresh sheep's glands). This latter medication has, barring the increased rate of the pulse and respiration, and an improvement in the peripheral circulation, been without any apparent benefit to the patient. He still remains in a stuporous condition, and while he will doubtless in time pass out of the state of catalepsy, he will not improbably emerge from it with more or less dementia, like many other cases of insanity which after the acute stage of a severe and prolonged nerve-storm has passed away remain but as the shattered fragments of their former psychic selves.

I am indebted to Dr. A. R. Moulton for his kindness in allowing me to publish the foregoing case.

THE STRUGGLE FOR LIKE LOBULE.

A Study of the Interior Temporal Gyrus.

By WALLACE WOOD, M.D.,
of New York City.

THE posterior base of the brain presents three swellings which, from their appearance, may be likened to root, stalk, and flower. These three swellings, as far as they have been investigated in human brains, have been rather looked upon as appendages of the three higher senses—smell, hearing, and sight.

I confess that my study of the brain of ruminants have led me to a different conclusion, which is, that these lobes are vital, belong not to the three higher senses, but are rather of the animus of the physique; that in the bull, *Bos taurus*, for instance, these lobes hold the animus of the bull tongue, and bull throat, and of the bovine corporosity, and the power of reproducing

and propagating the bovine race. They can be nothing else.

The rational inference is that in homo, a being that in many respects resembles this far from ignoble animal, these lobes have the same significance; that in them we are to seek the spirit of substantial living and lusty thriving, and sound propagating; in short, the root, stalk, and flower of the vegetative life. The dissection, preparation, casting, and photographing of the brains of something over a hundred ruminants have convinced me that the posterior spheres in bos and homo are homologous.

Is there a visceral or pectoral lobule? If a prepared brain be put into our hands for study, we trace and demonstrate first the fissures, Sylvius, superior frontal, middle frontal, superior temporal, middle temporal, etc. Next we demonstrate the convolutions, superior, middle, and inferior frontal, middle and inferior temporal, etc., but we are finally attracted by the various *eminences* of different shapes, the lobules, oval, quadrate, cuneate forms, which appear not only on the mesial, but also upon the cranial surface. After a considerable practice in brain preservation, brain casting, and brain delineation, one comes to feel more and more the form or force of these protuberances, lobes or eminences, which are literally thrust upon us.

The sphenoidal pole thrusts itself forward, the bulb of the overocciput projects its pope's nose backward, the cone of the underocciput protrudes itself like a draco from under a mons, the paracentral lobule in many brains is exceedingly salient. The inferior frontal has a lobule always strongly marked. One can hardly place his finger upon the cortical surface without touching an eminence, a morphe, a definite form, head or tail or body, a glomerus, a suggested spiritual organism.

Let us enumerate these eminences or lobules by position. They are as follows:

1. The sphenoidal pole.
2. The temporal eminence.
3. The underocciput.
4. The overocciput.
5. Quadratus and parietal lobule.
6. The paracentral lobule.
7. The medicentral eminence.
8. The infracentral eminence or lobule.
9. The metopic crest, or anterior metopic lobule.
10. The metopic foot, or posterior metopic lobule.
11. The talker in third frontal, the "pied."
12. The "cap," or head of the talker.
13. Posterior lobule of midfrontal gyrus.
14. Anterior lobule of midfrontal gyrus.
15. The prora.
16. The superorbital salience.
17. The pole of the insula.
18. The pole of the orbit.

We may add to these others, notably the lobule lying on the under surface between the sphenoidal pole and the occipital pole. It is found by a cortical swelling of the middle and inferior temporal gyri. It is the under portion which is in question.

Here, then, is this prominent bulge, sometimes lying more lateral, sometimes more medial. It appears enormous in the ruminants, shorter in cat and other carnivora.

The sphenoidal pole is gustatory, of this the evidence is conclusive. This stoma-looking lobule with its cross incision is the image of the glossopharyngeum, can be nothing else than the cerebral head of the glossopharyn-

geal nerve, together with associate centers. It is the chef and criterion, the lobule of the banquet. In its labyrinths are the spiritual representatives of the bountiful table of nature or of art.

The opposing pole, the occipital, the united gyri fusi-formis and lingualis, with terminal bulbs or ramps or lobules, from the superior or middle temporal, or the third occipital, or from two or all three of them, is the lobus genitalis. Its shape in primates is more or less palliform, and this form made up of stemons, ramps, or stamen-like or serpens-like double curves.

This, then, is the "burning bush," the ever budding "rod of Jesse," the fleur de lis "fairy tree," etc, the soul and maintenance of the life of the race, as its polar opposite, the sphenoidal pole, a veritable lobus succulentius, is the spiritual supporter or nourisher of the life of the individual.

Between the two lies the temperooccipital swelling. It is bounded by the auditory area, the genital area, and the gustatory area. To which does it belong or with which does it best associate?

Left hemisphere of deer from the Philippine Islands. The perpendicular fissure of Sylvius separates it into anterior and posterior. Posterior to this fissure is a great triangle—the temporal lobe. The anterior-superior portion is the superior temporal gyrus; the superior-posterior portion is the middle temporal gyrus; the inferior portion is the inferior temporal gyrus. Posterior is the genital lobule. The inferior temporal gyrus resembles a living creature—a worm, a seal, a hippocamp, or hippocampus, showing three parts—head, breast, and dura. This hippocampus is to be found upon human hemispheres as well as upon those of ruminants.

What is its function? Is it auditory? Is it gustatory? Is it an annex of the affection? Is it none of these? Is it all of these in association, with something added?

Is it not perhaps auditory, respiratory, and circulatory, and digestive; that it is a combined projection and association center for the acoustic, pneumogastric, the cardiac, sympathetic, phrenic and intercostal fibers?

If this is thoracic, pectoral, visceral, where is the mammalian lobule, the center for the breast? It must be here.

In the brain of cows I have seen a great blossoming in the temperooccipital region, but this blossom seems further posterior. Yet we remember that the bovine mammae are inguinal, not pectoral. In human brains I have often observed a curious papilla or coiled lobule at this particular point.

Upon the brains of herbivoras, deer, antelopes, etc., the inferior temporal gyrus takes the organic fusiform

shape—that of a swollen and sigmoid-flexed intestine. We seem to see the mouth or beginning, the belly or breast or swollen middle, and the end, like a vent or cauda.

We can hardly resist the temptation to believe that the beginning is glossopharyngeal, the middle pneumogastric, and the end pudendal or splanchno-pudic. In short, that it is a spiritual representation in the cerebrum of the course of the ingestive, digestive, and egestive tract.

Above it, in small ruminants, ramps the middle temporal, which here seems the tail of the temporal eminence or auditory lobule. Can this gyrus, perhaps, be both auditory and respiratory?

In a female human brain now in hand the temporo-occipital lobule appears in outline like two serpents ramping in a posterior direction, and, as it were, melting their heads together. These ought to be the projection gyres of certain afferent nerves, and we ask again is the area acoustic, or visceral, or pectoral? Perhaps it is all; now one, now the other, as spirit or matter strive for the place.

Anterior to this glomerus, in the specimen mentioned, is the great succulent stome or sphenoidal pole, while posterior to it is the anthos—the flower. Shall we be safe in calling it the lobus vitalis, valens, robustus, as the other two are the lobus succulentius or gustatorius and lobus propagatorius?

The suggestion is that this swelling is visceral, pectoral, thoracic—that it is the “haemal tube” center. If so, is it not the vital knot which the wrestler strains upon when he advances for the final grapple with his antagonist? If so, it is of cardinal importance, for it would be the animus or spirit of the struggle for life.

I do not see how it is possible, in the light of comparative anatomy, for the under surface of the brain to represent anything very lofty or spiritual. It seems to me rather as the soul of the vegetative life.

It is, then, the disheartening and discouraging lobule—that is, when it is small, feeble, and mean (I have a brain—a case of lypemania—in which it is completely atrophied); it is the lusty heart and vigorous lobule when it belongs to an ox, or a horse, or an athlete. It is an invalid lobule when it belongs to an invalid; it is staunch in the youthful and well nourished.

Succulence and corpulence are the main characteristics in the physique *et morale* of the domestic swine, as of the stall-fed ox, and these spirits swell and fill the lowest parts of the brain, just as salience and insolence are the two striking features in the physique *et morale* of the wildcat, which two spirits rise to the highest point of the brain.

If, therefore, the sphenoidal lobule is glossopharyngeal and esophagic, a lobule of the animus gulae, and the lobule immediately following it contains the animus of heart and lungs, the animus visceralis, or vitalis, or robustus, or valens, is it not the center for the stout heart, the heart of the bull, the heart of oak? Would it also be the fumus, thumus, thumoleon or cœur de lion? Would it be the lump of courageousness? Would it not be the part of the soul referred to when we say, “Come, pluck up heart, let’s neither faint nor fear”?

It is true that courage is a large word—animus, virtus, audacia—and that courageous is a still larger—animosus, acer, audax, fortis—Luys located the quality in the cerebellum, but a strong heart, strong lungs, strong thorax seems to be the proper physical basis.

These, then, are animated by the two nervous or unconscious centers, the cerebellum and medulla oblongata, and also by the higher or gyral centers, namely, by the very prominent front-lateral lobule that strikes, bites and roars; and the equally prominent inferior temporal droop, the lobule under discussion, in which perhaps resides the soul of heart, lungs and thorax.

The valens, the valient soul, the vrai cœur de lion, may be a powerful band of association fibers connecting the two. Courageousness fears nothing and can overcome anything.

Fear strikes to the heart. Where does it strike the heart? Love emboldens the heart. Where does it embolden the heart? Where is the local habitation of gallantry, bravery? Is there a cogitation center under the temporal eminence, a pneumocardogastric center? Yes.

VENESECTION IN PNEUMONIA FOLLOWED BY INJECTION OF NORMAL SALT-SOLUTION.¹

By WILLIAM PORTER, A.M., M.D.,
of St. Louis.

The suggestion that I have to offer is founded upon something more than a mere hypothesis. The physician of 20 or 30 years ago, bled in cases of threatened cardiac failure in pneumonia, and the good results led him to bleed again. Within the last year or two, the modern physician has injected the normal salt-solution in cases of lobar pneumonia with advantage. It is a fair proposition that these two procedures can be combined, and while by venesection we attempt to relieve the tendency to right-sided heart-failure and remove a certain amount of toxin-laden blood, we at the same time, by means of the salt-solution, increase the pulmonary circulation, accomplish dilution of the toxins that remain and increase the oxygen-carrying capacity of the blood.

I shall here use the term pneumonia as having reference to the lobar or so-called croupous inflammation, distinct in cause, progression and manner of resolution from the bronchopneumonia or lobular form. May I remind you of the classical distinction of the schools, that the former is an acute, general disease with local manifestations in the lung, and the latter is a local disease with general manifestations? In the typical or lobar form, the attack is accented upon the heart and the nervous system. The organic lesion in the lung may be extensive and respiration and circulation be fair, while on the other hand the heart may fail where there is but little lung-invasion.

The character of the blood in pneumonia and the condition of the blood-supplying organs is a large field for study. Upon deductions from such investigations, the most rational and direct methods of medication may be based. The impression upon the nervous system in pneumonia is also an important factor. I believe that instead of three stages, as we find enumerated in the books, we have four, and that the first stage is that of vasomotor paresis dependent upon toxin poisoning, of which the main symptom is the feeling of general malaise and the climax, the chill that inaugurates the so-called first stage of the books.

Certain is it that vasomotor inability is a prominent and anxious complication as far as, and at times beyond, the crisis in the last stage. This adds to the

¹ Read at the Annual Meeting of the Missouri State Medical Association.

necessity for investigation along the lines that I have mentioned. If the toxin-poisoned blood with its excess of fibrin can be brought nearer to the norm, we should expect that the nerve-force which this blood supplies will be stronger and that favorable resolution will be hastened.

What is the condition of the blood in pneumonia? Granted that there is a pneumococcus infection—and we do not have to argue this in this Association—we quickly have a toxemia due, as shown by Wells,¹ to the development of pneumococcal toxins and possibly antitoxins. This writer also says that the blood may contain pneumococci as well as toxins, at first following the infection, the specific gravity of the blood is increased and also the number of white-blood corpuscles. Whether this leukocytosis is protective or not is an undetermined, interesting question. We find with it an increased amount of hemoglobin and fibrin. The proportion of the latter in the blood is sometimes 5 times as much as in the normal. In this condition of the blood, with depressed cardiac force, the tendency is often to the formation of heart-clot, which occurs in about 1 case in 20, and is doubtless in many instances believed to be heart-failure.

Time will not permit me to speak of the destructive changes in the blood elements, but there are two additional phenomena that have a decided bearing on our subject. One is the great diminution of the chlorids and the other, lessened capacity of blood aereation.

Absence of the chlorids from the urine in pneumonia cases has been noted by many diagnosticians. A typical report was made by H. Hutchinson,² of London, who found a greatly increased quantity of chlorids in the urine of a number of pneumonia cases and there was no vicarious excretion through the skin, intestines or sputum. The blood was also poor in chlorids. It is true that other acute diseases are characterized by the retention of chlorids, but not to so marked a degree as pneumonia. The tissues contain a little more than the norm, but it is not stored up in any special organ.

The blood-changes affect the nervous system, and with the increase of the pneumococcus toxins there is the initial chill, the subsequent fever and the vasomotor depression. The lowering of arterial tension in the early stages is due, according to the most recent investigations, to the inhibitory action of the toxin upon the nerve-fibers of the capillary walls and bloodvessels and not to direct heart-failure which may occur later, from a blood-clot or loss of nerve-supply to the cardiac muscle. With blood so changed and the mechanism of the circulatory organs so impaired, the capacity for aereation is greatly diminished. May not this explain why, in many cases where there is a comparatively small amount of pulmonary lesion, there is the rapid respiration, the quick pulse, the high fever and general depression of an exceedingly acute and grave disease?

Upon this premise we have a better understanding of the record of results following venesection in former days and a good cause for its reintroduction to the practice of today. Upon this theory, it is not so much the relief of the heart that is needed, or a lessening of the pressure in the inflamed lung, as it is a withdrawal of as much of the toxin poison as is possible, a lessening of the amount of fibrin and a restoration of the air-carrying and nutritive capacity of the blood.

I regret that the clinical experiments at the City

Hospital, under the management of Dr. Amis, are not far enough advanced to make us willing to quote them. A careful record of all the attending phenomena is kept and the promise is good, but we all recognize that in estimating results in any new method, conservatism is demanded. In private practice so far I have limited the use of the salt-solution to enemas, but will use it whenever indicated hereafter.

Since writing this paper several cases have been treated as above indicated, with good results. One marked case in Division 10, care of Dr. Apepen, of marked lobar pneumonia of the right lung, with threatened heart-failure complicated by violent delirium tremens, was bled to the extent of 18 oz. on the day after admission, and normal salt-solution of 24 oz. injected. No other treatment except strychnia was used and the patient made a good recovery. The immediate relief was most marked in this case.

This method is justifiable, first because venesection is in itself a step in the direction of relief of poison-infiltrated and overcrowded bloodvessels, and because the injection of the normal salt-solution is an effort to restore the blood to its normal condition. A reference to the records of the past and study of the results of more recent investigations of hemic changes in pneumonia will sustain the first proposition. I believe that venesection alone is a remedy that is too often neglected, especially in sthenic cases.

The second step in the procedure, especially when it is made the second and not advanced alone, is also reasonable. Penrose² records that by the infusion of the salt-solution in several cases, the toxins were diluted, delirium relieved, and elimination through the sweat-glands and kidneys promoted. The temperature was lowered and the heart stimulated. Penrose did not precede the saline infusion by venesection, but advocates the latter, should the circulation seem disturbed by the additional volume of liquid. I believe that venesection should be done first for the reason already given, and also that it is a most important and reasonable preparation for the injection.

Lenhartz⁴ found that the immediate result of intravenous saline injections in acute diseases in children was to lower the blood-pressure and increase the force of the heart. The consequent lavage of the whole system aided diuresis and diminished the toxins. The number of the blood-corpuscles and the hemoglobin and blood-pressure did not show much increase, but the excretion of sodium chlorid became rapid, and the high specific gravity of the urine showed that a large quantity of waste was being eliminated.

The saline injection is shown by Reid Hunt, of the Johns Hopkins University, to increase the amplitude of the respiratory undulations of the blood-pressure, and Penrose believes that this indicates that the salt-solution increases the circulation in the lungs, and their ability to take up more oxygen. He also believes that the patient is more susceptible to the influence of oxygen inhalations.

In the experiments at the City Hospital, venesection is ordered as soon as the diagnosis is well established, *i. e.*, within 4 days at farthest from the initial chill, and generally earlier. The amount of blood to be removed is not necessarily large. More can be removed if necessary, and until this method of treatment is better established, it should not be pushed to extremes.

⁴ *Annales de Médecine et Chirurgie*, September, 1899.

From 8 to 12 ounces will generally give relief in the average cases as we meet them, and the class of patients that come to the hospital. At once, the subcutaneous injection of the salt-solution is ordered, giving this the preference over the intravenous injection because it is slower and the effects more gradual. In an urgent case I should not hesitate at transfusion.

A most convenient method of preparing the normal salt-solution is a modification of Jennings' condensed solution. In this the potassium chlorate is lessened and the amount of the sodium chlorid increased. There is also a smaller amount of the phosphate. My reason for the change is the seeming greater demand for the sodium chlorid. The solution is:

R.—Sodium chlorid.....30 grains.
Potassium chlorate.....60 grains.
Sodium sulfate.....60 grains.
Sodium phosphate.....40 grains.
Sodium carbonate.....60 grains.
Distilled water to make..... 6 fluidounces.
One part of this solution in sixty of distilled water.

I hope that further investigation may justify this method as an addition to our treatment in pneumonia. I use the word addition advisedly, for it should be by no means a substitute. The very pathological conditions outlined demand the greatest care in the ordinary methods of promoting elimination by the skin, bowels, and kidneys, and above all, of heart support. The value of oxygen in cases of greatly impaired aeration is not sufficiently understood. It seems to be especially useful after the injections of the salt-solution.

Heart tonics should be chosen according to the indications. It is not so much a question of a heart tonic in an urgent case as what kind of a tonic. Strychnia is nearly always indicated, and digitalis, if there is vascular relaxation and an easily compressible pulse. The well-known effect of nitroglycerin on the muscular coats of the arteries, and, as some think, upon the vasomotor system, should limit its use in pneumonia to the few cases of high-pulse tension with cardiac failure. On no account should heart-depressants be used, even in the first stage, to lower arterial tension, which is undoubtedly due to toxin poison. Diminish the toxins and guard the heart.

I have had no satisfactory experience with the anti-pneumococcus serum. It is yet a question that is to be solved. The general treatment of pneumonia, however, is too large a question to be discussed in a paper intended to call attention to a single proposition.

HYALIN CASTS PRESENT IN PUERPERAL ECLAMPSIA.

By L. NAPOLEON BOSTON, M.D.,
of Philadelphia.

Bacteriologist to the Philadelphia Hospital and to the Ayer Clinical Laboratory of the Pennsylvania Hospital; and Demonstrator in charge of Clinical Laboratory in the Medico-Chirurgical College, Philadelphia.

THAT the urine from cases of puerperal eclampsia always contains casts, is a statement none can doubt; however, when the urine is alkaline—a condition which I have never observed—no casts would be found present, yet they might be formed in the kidneys in great numbers. A probable reason for the statement that no lesion of the kidney is present in eclampsia, is, that in searching in the urine for the anatomic elements of

renal disease (casts) we overlook them, by reason of our using the power of illumination usually employed for the study of casts.

The commonest form of casts present is in its refractive power and transparency similar to the casts found in chronic interstitial nephritis (hyalin), while the morphology is widely different. These casts are usually long and broad, with highly refractile centers and a faint, whitish outline or border, just inside of which is seen a narrow band of a dull pearl tint. They are broken squarely or obliquely at one or both ends, while

FIG. 1.—Casts found in urine, obtained by catheter between convulsions. Eyepiece IV, obj., Queen 1-6.

it is quite common to find one extremity markedly tortuous, transcribing many coils and occasionally tapering slightly. The above forms of casts comprise nearly all present, yet a few granular casts are to be found, and it is the finding of this variety that causes the examiner to conclude that there are but few casts present. I have repeatedly found persons studying carefully a granular cast when only a moderate change in the amount of light enabled them, by careful focus, to view the same field filled with the above-named varieties. This hyalin variety of casts may safely be regarded as

FIG. 2.—Casts from urine of a case of puerperal eclampsia. Eyepiece II, obj., Queen 1-6.

the most difficult form to detect, and unless the examiner is on his guard, they may escape notice. Under a low-power lens (2-3), many of these pale casts are readily seen; but when an attempt is made to bring them into focus under a higher power, 1-6 or 1-8, we at once notice that the definition is not distinct, and that the most careful adjusting of condenser, lens, and diaphragm are necessary. Here may be the opportune place to speak in reference to the need of a condenser and an iris diaphragm in the study of urine. I have never been able to see, under a 1-6 or 1-8 lens, the form of casts under discussion, without their aid; and while we commonly hear that these accessories to the micro-

scope are only necessary for the study of blood and bacteria, such statements are misleading, incorrect, and must emanate from persons who have overlooked the finer points in microscopic urinalysis. There is no task more difficult, in the field of medical microscopy, than the satisfactory study of hyalin casts.

Tapeworm-form casts are quite common, and this variety frequently resembles the so-called amyloid cast. A peculiarity of the casts present* in the urine from eclampsia patients, is, that they are easily preserved by adding a few drops of chloroform, or a weak solution of bichloride of mercury to the urine, which usually causes casts to become darker, and later to disintegrate; while these varieties may show little or no change for several weeks. It is singular that the urine may contain no casts in from 24 to 72 hours after delivery. In one instance, a case seen with Dr. F. K. Brown, of this city, the woman had many convulsions before delivery, which was accomplished by rapid dilation of the cervix and the use of forceps, under ether-anesthesia. The patient remained unconscious for 15 hours after delivery, yet the urine, voided on the third day, did not contain casts. In all fatal cases observed casts have been present in the urine obtained a few hours before death; while their disappearance from the urine, after delivery, has been a favorable symptom. Figs. 1 and 2 were sketched from specimen slides, permanently mounted.

REPORT OF A CASE OF FOREIGN BODIES IN THE BRAIN.

By CLARENCE A. GREENLEAF, M.D.,

of Rochester, New York.

Assistant to the Staff of the Rochester City Hospital.

THE exact location of foreign bodies within the cranium is an absolute necessity to determine whether or not operative interference is feasible or advisable. While cerebral localization shows, to a certain extent, what structures have been injured, it gives no evidence of the size, nature, and situation of a suspected foreign body. By the use of the x-ray, however, exact localization is possible, as illustrated by the following interesting case which I am permitted to report through the courtesy of Dr. E. M. Moore, Jr.

The patient, a male, 37 years of age, shot himself in the head with a 22-caliber bulldog revolver in 1889. He fired 3 shots, holding the revolver at the right side of his head behind the ear. The patient states that he held the revolver in the same position while firing the first two shots, but that when he fired the third he moved his head forward. He immediately became unconscious and was removed to St. Mary's Hospital and placed under the care of Dr. E. M. Moore, Jr. Examination at this time revealed one wound upon the right side of the head and a second one over the occipital protuberance. The first one penetrated the skull, while the second was a simple scalp wound. He remained unconscious for 3 weeks. He remained in the hospital for 3 months, although the external wounds were healed at the end of 3 weeks. At the time of his discharge from the hospital the patient had no symptoms except a paretic condition of the right leg and a left heminopia. In April of this year the patient consulted Dr. Moore again, hoping that something might be done to relieve him of his continued disability. A physical examination made at this time showed the following conditions: A depression upon

the right side of the head about the size of a ten-cent piece 6.5 cm. posterior to the upper margin of the right ear and a linear scar about 1.5 cm. long just above the occipital protuberance. Neurological examination shows the gait of the right leg to be paretic, of the left leg normal. Station is good with eyes closed. There is no voluntary motion of the toes of the right foot. Flexion of foot, extension of leg and flexion of thigh are weakened. The muscles of the foot react to strong faradism. The grasp of the right hand is 50 pounds, of the left 48 pounds. The difference in the circumference between the right and left thigh is $\frac{1}{2}$ of an inch,

FIG. 1.

while the circumference of the right and left calf are equal. The right kneejerk is exaggerated, while the plantar reflex is normal, but produces no movement of the toes. There is a slight ankle-clonus upon the right side. There is no disturbance of the sense of touch; the sense of taste is diminished, principally upon the right side of the tongue which is protruded slightly to the right, although movement to both sides is possible. The sense of smell is somewhat diminished in both nostrils; the hearing is good in both ears. There is no disturbance of the sense of pain. Aphasia, word-blindness and word-deafness are absent and the memory and general intelligence are good.

FIG. 2.

Ophthalmological examination reveals a lateral heminopia of the left side. Figs. 1 and 2 show the patient's field of vision. V. O. D. $\frac{1}{2}$ V. O. S. $\frac{1}{2}$. Ophthalmoscopic examination is negative.

X-ray Examination.—Fig. 3 is a lateral view and shows a distinct shadow denoting the presence of a bullet in the brain. This shadow is 4.5 cm. from the upper surface of the skull and 6 cm. from its posterior wall. There is also a fainter irregular shadow which probably indicates an organized blood-clot, about 2.5 cm. in diameter, situated 0.5 cm. posterior to the bullet. A distorted shadow is seen in the lower posterior part of the head. Fig. 4 is an an-

* New York Medical Journal for November 4, 1899. Monatsberichte über die Gesandtheiten auf dem Gebiete der Krankheiten des Harn- und Sexual-Apparates, May, 1900.

teroposterior view showing two distinct shadows. The upper, more rounded one corresponds to the shadow of the bullet shown in the lateral view. The lower one is more distinct in Fig. 4 than in Fig. 3 on account of the distortion produced by the distance of the foreign body from the plate. Measurements of the radiograph from which Fig. 4 is made

FIG. 3.

show that the distance of the upper foreign body from above downward, is the same as in the first plate, and that it is located 4.4 cm. from the lateral wall of the skull. The lower shadow or bullet is 8.2 cm. from the inner wall. The nature and extent of the hemianopsia indicates that the lower foreign body lodged in the right optic tract and its location

FIG. 4.

as demonstrated by the x-ray corresponds exactly to this position. Fig. 5 is a schematic illustration of the optic tract, and the location of the bullet.

This case presents a few points of special interest:

1. The question of the brain areas involved in the injury as shown by the symptoms and the result of the neurological and ophthalmological examinations.
2. The value of the x-ray in determining, not only

the presence of the foreign bodies, but also their location. 3. The value of the x-ray in determining the feasibility or advisability of operative interference. In this case it is apparent that an operation for the removal of the foreign bodies is out of the question. It is a remarkable fact that during all these years the symptoms

FIG. 5.

have remained practically stationary, and this fact is also an argument against operative interference, even if it were possible, as the result would be extremely doubtful. Another question to be considered is whether one or two bullets entered the brain, and whether, if one only entered, it divided as it passed through the bones, as in a case reported by Tuffier (*La Presse Médicale*, December 20, 1899). The patient states that he fired two shots with his head and the revolver in the same relative positions. There was only one wound of entrance and this would seem to confirm the above statement. The radiographs, also, show one complete circular shadow and another flattened or crescent-shaped in an entirely different plane, from which we may conclude that there are two distinct bullets.

I am indebted to Dr. Wheelock Rider for the ophthalmologic examination and to Dr. Robert G. Cook for the neurologic examination.

THE ELECTRICAL TREATMENT OF UTERINE FIBROIDS.

By GIDEON C. SEGUR, M.D.,
of Hartford, Conn.

By the electrical treatment I mean the application of the galvanic current. Its application is indicated in cases of uterine fibroids in which the symptoms of pain and hemorrhage, one or both, are pronounced, and may be used when they are absent for the purpose of promoting absorption and thus reducing the size. I use a battery consisting of 45 Leclanche cells, with a cell selector, whereby any one or more of the cells can be connected in the current; a switch by means of which the poles can be changed; a current controller, by means of which the current can be gradually increased or diminished without shock; a milliamperemeter to register the exact dosage; a large clay electrode 6x8 inches, which is usually applied to the abdomen attached to the positive pole, and a series of amalgamated or steel uterine electrodes of various sizes.

As early as 1871, the treatment of uterine fibroids by galvanism was begun by Ephraim Cutter; the applica-

tion being made with electrodes, consisting of two small needles introduced into the uterus through the vagina, in his first case, August 21, 1871. In other cases one needle in the uterus and a sponge electrode placed over the pubis. Most of his cases, however, of which he reported 50 in 1887, were treated by puncturing with both electrodes, attacking the most prominent portions. Improvements in application were devised by Apostoli early in the eighties, as a result of a careful study of the subject, and consisted in the intrauterine application of the negative pole and a large, close-fitting, external, positive pole, for which sculptor's clay afforded the best material. Many conscientious practitioners, notably Thomas and Skene, Keith, of London, A. Laphorn Smith, of Montreal, A. J. C. Skene, Augustin Goelet, G. Betton Massey, E. H. Grandin, and others have been successfully using it in their practice for years. While the ordinary physician lacks the confidence and skill requisite to perform the necessary surgical operation for the extirpation of these growths, he can at comparatively slight expense place himself in a position to at least symptomatically cure a very large percentage of these cases.

There is nothing in the armamentarium or in its application but that can be readily learned by an intelligent physician. It requires time and patience to keep the appliances in perfect order, and to make the necessary applications. These are the principal objections, if objections they be, to its use.

The usual care and attention to asepsis which is given by the painstaking surgeon, should apply in this treatment. An antiseptic douche should precede the treatment, and it has been my custom to introduce a speculum and cleanse the vagina thoroughly with Dobell's solution and also the canal before introducing the electrode, which should also be aseptic. I prefer to introduce the electrode through the speculum before removing the latter, which can be again inserted before the electrode is removed, the condition noted and suitable applications made. When the os is very sensitive, an application of cocain can be made rendering the introduction of the electrode painless.

By means of the Bailey improved rheostat, the current can be increased so gradually as to produce no shock (usually no sensation within the uterus, a feeling of warmth upon the abdomen under the positive electrode) until the patient experiences a sensation of tension within the uterus and a burning sensation under the abdominal pad, when a rest can be taken. Tolerance will soon prevail, and an increased amount of electricity can be applied, depending upon the strength, disposition, and nervousness of the patient. The amperage will vary from 40 to 60 milliamperes. My experience has been, that a stronger current can be borne but for a very few minutes, and causes extreme exhaustion, oftentimes dizziness and faintness, so that I never now push the current above that dosage which the patient can tolerate without too much effort, but continue its application for a considerable period, often as long as thirty minutes.

I believe that by this method of application, as good results have been achieved as by the use of a stronger current for a shorter period. Nearly as much care is necessary in diminishing the current at the close of the seance to avoid shock, and I often employ five minutes, reducing from 60 milliamperes.

The most ardent advocates of the electrical treatment of uterine fibroids do not claim that it will cure every

case of a fibroid nature, although the conviction is strong that it will do so in uncomplicated cases, viz., that where it does not succeed, there is some degenerative process present, such as a cyst or an abscess within the tumor or a breaking down of the epithelium, from some cause, in which the application does not have a curative but sometimes an irritative effect. In these cases the application does no harm, but really good in that it assists in the formulation of a correct diagnosis and points the way to a more radical and serious method of treatment.

I have selected three cases from my records to illustrate my experience with this treatment.

CASE 1.—Mrs. K. P. (B.), aged 32, was treated in March, 1889, for chronic metritis, retroflexion, and dysmenorrhea. The retroflexion was overcome and the inflammation readily yielded. November 18, 1890, she returned, complaining of menorrhagia since the last menses, October 10; before that time her flowing had been scanty; shortness of breath; abdomen bloated; constipation; urine, light colored and frequent, very free and ammoniacal; appetite, voracious; left temporal and occipital headache, and pain in sacral region. Examination—Uterus enlarged, sound passed readily 3½ inches. Posterior and to the right is a mass associated with the uterus, as large as a turkey's egg, and somewhat sensitive. Local treatment, consisting of douches, applications of iodine and tampons medicated with belladonna, iodoform and glycerin were used and ergot ½ dram three times daily after meals. Early in December she had a severe cold, and developed a peritonitis which confined her to her bed and aggravated her condition. She grew steadily worse, the tumor increasing in size, and another developing upon the right side extending anteriorly. An application of galvanism was made first, February 7, 1891, a large clay positive electrode applied to the sacrum and a large sponge (negative) in left inguinal region. The current was gradually carried to 20 milliamperes, as gradually reduced, the poles changed and the same process repeated; iodine to cervix and vault belladonna and iodoform tampons; potassium iodid 30 grs. internally, three times daily. Treatment, February 13. No pain after last treatment; intrauterine negative (3½ inches); sacral positive 10 milliamperes for 10 minutes, local applications repeated. Third treatment, February 28. Menses February 16 to 20—not very free, only little pain. Has been feeling good. Intrauterine negative from 10 to 25 milliamperes for 10 minutes—iodine, etc. Fourth treatment, March 7. Has had pain since March 2 inside, low on left, no discharge; intrauterine negative 25 milliamperes 15 minutes. Fifth treatment, March 24. Menses 10th to 17th, considerable pain, and flowed freely; since 17th has had much lameness in arms and legs. Intrauterine positive (10 milliamperes 5 minutes) followed by negative 25 milliamperes for 10 minutes, also faradism, from feet to hands; potassium iodid, 5 grs. three times daily. Sixth treatment, March 31. Pains all over still continue. Not much discharge after last treatment. Intrauterine negative to 30 milliamperes for 20 minutes; faradism from feet to hands. Continue potassium iodid, increasing 1 gr. daily till taking 10 grs. three times daily. Was not seen again till June 4, when she reported that she had not felt so well in five years. Uterus very mobile, and very little sensitive, tumor about as large as my fist, posteriorly and to the right; sound passed 3 inches. July 25, has been regular with menses, less free, no pain, little leukorrhea. No inflammation of uterus, continue potassium iodid, 20 grs. three times daily. November 6, 1891. Regular menses each month—about five days—usual amount, no pain; stopped potassium iodid in September. Notices enlarged abdomen, but has no inconvenience; this month some leukorrhea. An examination shows fibroid smaller, depth of canal 2½ inches, no sensitive-ness.

In this case the pain was relieved by the electricity upon its first application, the electrodes being applied externally and the current only carried to 10 milliamperes. The intrauterine positive application (10 milliamperes 5 minutes), March 24, at time of fifth treatment, controlled the menorrhagia, and after the sixth treatment, there being no more pain or hemorrhage, and the tumor having largely dimin-

ished in size, the electrical treatment was discontinued and the iodid continued, which, being well tolerated, she was enabled to take for two months. May 22, 1900: Says she has never had any trouble since her treatment in 1891, is perfectly well. Examination shows no tumor, uterus retroverted, the fundus being attached to the sacrum, no sensitiveness.

CASE 2.—Mrs. D.W. C., aged 40, married 15 years. (March 23, 1898) Housewife. One labor, 6 years ago. I first saw her at boarding-place, writhing with abdominal and lumbar pain with which she had been suffering for several days. The abdomen was tense and sensitive; some slight bloody discharge; pelvis by digital examination seemed filled with dense hard, inflammatory exudate. Perfect quiet in bed. Hg. Cl. douches and suppositories of aristol (gr. iij), opium (gr. ij), and belladonna, gr. $\frac{1}{4}$, enabled her to come to my office March 30. She had been suffering from pain in lumbar region, down back to right knee for years, but much worse the past month, and extended to left side and across abdomen, incapacitating her for her household duties. Bowels usually irritated by cathartics; movements light and thin like a child's. Feels tired and has no ambition, appetite poor, nothing tastes good; very nervous, easily excited and sensitive. Has much headache, frontal or occipital, sometimes with nausea and vomiting. Restless and cannot sleep; sometimes lies awake 3 and 4 hours. Catamenia began at 13; last occurred March 5, to March 7, recurs every 4 weeks; amount always small, lasting 3 or 4 days. For a week before period has severe pains "all around," diminishing after flow is established. Has a thick, light-colored leukorrheal discharge most of time, for which has used douches more or less. Examination—Fistulous opening at left and anterior to anus; passed probe 4 inches. Large uterine fibroids filling pelvis, making a dense, hard, irregular-shaped mass with indications of intrauterine breaking down. A palliative treatment of iodine with glycerin tampons was given, and she returned in one week for an electrical treatment. This treatment was intrauterine negative, sacral positive to 15 milliamperes for 6 minutes. No pain was caused, slight bloody discharge followed removal of electrode. The positive external electrode was placed upon the sacrum because of localized pain there. April 13: Second treatment of 20 milliamperes for 8 minutes was given, with the same application of the electrodes. April 21: Third treatment of 40 milliamperes for 10 minutes was given vaginal negative, sacral positive, the position of the tumor being so changed as to make it impossible to enter the cervical canal. May 5: Fourth treatment of 40 milliamperes for 10 minutes was given vaginal negative, abdominal positive, and borne nicely. Her menses April 26 to May 1 were attended with much pain but were more free than usual; says she is feeling finely. May 12. Upon inquiry as to how she was feeling said, "I am dancing all the day; free from pain." The fifth treatment, similar to the last, was given to 50 milliamperes. June 2: The tumor has so diminished in size as to enable me to rotate it sufficiently to bring the cervix forward and to stretch it with graduated dilators, so that the intrauterine electrode could be inserted $1\frac{1}{2}$ inches. Eleven treatments in all were given, the last being upon August 11.

CASE 3.—Miss C. O. B., age 40, housekeeper, was brought by her family physician for consultation February 26, 1891. For 5 years her menses had been increasing in duration and amount until there was only one week's respite each month, and much blood in hemorrhages, which came on suddenly and recurred frequently so that she was obliged to keep very quiet and in bed much of the time; much pain in sacral and left inguinal regions and left leg from which she is seldom free. Is very much concerned about herself, fearing she will never get any better without an operation and dreading that. The left side of the pelvis was filled with a fibrous growth which was irregular in outline, and extended upward to a level with the umbilicus; another growth was attached to the fundus. She willingly acceded to my advice to try what electricity would do for her (while awaiting the menopause), and treatment was given at once, consisting of an intrauterine negative application carried to 25 milliamperes, and lasting 10 minutes. These treatments were repeated March 5 and 25, April 1, 8 and 23. When she came for her sixth treatment, April 29, she reported: "No pain in back. Am able to go up and down stairs, stepping with each foot for the first time in 5 years."

I will not enter into detail respecting her treatment at this time, but will summarize it by stating that her treatment continued over a period of 5 years, during which 80 applications of electricity were made (the last being given January 17, 1896), the highest amperage being 60 milliamperes, tolerance being the guide, and the time of treatment being from 20 to 30 minutes. Several times, dilation of the cervix, once under ether, was performed and several times vaginoabdominal applications were made. There were times when the tumor seemed to grow rapidly and there would be a recurrence of the old symptoms to some extent, but a few treatments would again reduce the size and relieve the distressing symptoms and we would both be encouraged. She entered heartily into cooperation with me in her treatment, and to that fact is due the beneficial results. Her physician informed me that: "She is well and strong. Her abdomen has diminished in size during the last few years. She has had no hemorrhage during the past 5 or 6 years, is perfectly satisfied that her treatment was by means of electricity and not with the knife, and would recommend it for conditions such as her's was 10 years ago."

In the discussion of this subject I have secured the cooperation of some of the most experienced gynecologists who have given special attention to this method of treatment.

1. Dr. Howard A. Kelly reports, May 12, 1900:

"I have had one most interesting case of a fibroid uterus treated for years most thoroughly by Apostoli, in Paris. The patient continued to have excessive hemorrhages, and I this winter did an abdominal hysterectomy. Microscopically there was no evidence of the electrical applications. This is my only recent experience."

Respecting this treatment, Dr. Kelly tells us (*Operative Gynecology*, vol. ii., p. 354). "The galvanic electric current is probably the most efficient means of controlling hemorrhage, and producing such permanent surface changes in the uterine mucosa as will tend to prevent its return."

2. Augustin H. Goelet, under date of May 12, 1900, says:

"That after most diligent and painstaking trial of this treatment, I have come to the following conclusions, viz.: (1) It is applicable only in interstitial growths of moderate size, and has better effect upon myomatous growths; (2) I have never seen a tumor of this kind (fibroid) disappear under its use; (3) It does, in some cases, effect considerable reduction in the size of the tumor; (4) It will relieve the symptoms produced by these growths, when it is used appropriately; it will relieve pain, congestion and pressure symptoms, and will arrest hemorrhage, but the relief is not always permanent; (5) Coincident with the local improvement there is always a marked improvement in the general condition of the patient; (6) It does not, *per se*, produce adhesions, but, on the contrary, with the shrinkage of the growth, adhesions which had existed previously are stretched and in some instances torn loose. It is a mistake to suppose that electricity will produce adhesions when it is used in a proper manner. When numerous adhesions are examined in these cases, on opening the abdomen after electricity has been used, they have either existed previous to its use or it has been used improperly. The introduction of unclean electrodes, or the carrying of infection into the uterus from the vagina, would certainly set up inflammatory action and tend to produce adhesions, but that would be no fault of the agent employed."

3. G. Betton Massey, who has without doubt had the largest experience in this treatment of any practitioner in the country, writes May 13, 1900:

"Am applying the methods daily with but slight modification. The only comment called for by me is one of regret

that so many surgeons should still persistently ignore the facts that have been marshaled in favor of this treatment in their published papers, many of them dismissing the subject in a line of mere condemnation. It is a satisfaction to know that many others are quietly using this method, and getting excellent results, even though they write little for the journals, so that, on the whole, I feel confident that the Apostoli treatment is steadily on the increase amongst those physicians who are willing to give it a patient trial in suitable cases. Those surgeons who wish to use the knife only, will of course condemn it, and we ask too much of average human nature to expect them to act differently. The slight modification that I said I now make in the method, refers to the use of an amalgamated gold or copper electrode whenever the bare intrauterine pole is positive. I now use this invariably, securing a diffusion of antiseptic mercurials coincident with the electric action.

Dr. A. Laphorn Smith, of Montreal, an early pupil of Apostoli, who was largely instrumental in introducing this treatment into this country, writes under date of May 19, 1900:

"1. Owing to the great improvements in technic, my last 10 hysterectomies for fibroid all recovered; 7 in 1899, and 3 in 1900. Some of them were very large tumors. 2. I am gynecologist at 3 hospitals, and one very large dispensary, so that I am very much pressed for time, being also a professor in the college here and having my private practice besides. For these two reasons I am using electricity much less; but I have just as much faith in it as ever. And I have good reasons for believing in it, for I meet many patients in the streets of this city, who were invalids from fibroid tumors who were cured by electricity, and are now well. Out of 102 patients who came to me with fibroids from all over this continent, 65 have been completely cured of their symptoms, so that they have not required to consult a physician for them since; and several of the others were benefited, although not cured. While the failures were all those who could not bear a high current, some of these were afterwards operated on and found to have badly diseased tubes and ovaries. So that, while circumstances prevent me from giving it the preference, I can still strongly recommend it to those who are not compelled or enabled to make themselves abdominal surgeons, as I am obliged to be."

CONCLUSIONS.

1. Electricity properly applied may be considered a specific for the treatment of uterine fibroids.
2. A moderate dosage, 40 to 50 milliamperes, applied for 20 to 30 minutes relieves pain and influences a diminution in size.
3. There are no dangers to be feared from its use if carefully conducted.
4. Puncture is not necessary in order to obtain practical results.
5. No serious operation should be undertaken until after electricity has been tried.

CONGENITAL UNILATERAL PTOSIS WITH ASSOCIATED MOVEMENTS.

By FREDERICK KRAUSS, M.D.,
of Philadelphia.

Eye-Surgeon to St. Christopher's Hospital Dispensary.

This singular condition, which is barely mentioned by many authorities on diseases of the eye, and entirely overlooked by others, is of sufficient rarity to be interesting.

Swanzy, who devotes much attention to this subject, states that "there are only 30 cases on record. It is most commonly the left lid that is affected, and the paralysis may be congenital or acquired. These conditions have been observed, viz., elevation of the drooping

lid when the eye is adducted, when the eye is abducted, or when the mouth is open.

"A synchronous contraction of the pupil has been noticed in some cases, while in some the elevation of the lid occurs also with a lateral motion of the jaw and with deglutition. Gowers' explanation is that in these cases the levator is not wholly supplied by the third nerve, but partly by nerve-fibers which in the third variety take their origin in the nucleus of the fifth pair, and which also supply the external pterygoid and digastric. . . . Needless to say, no remedy can be applied for relief of this condition."¹

The characteristics of the case cited below are as follows:

1. Complete ptosis of the left lid upon attempted binocular vision.
2. Complete elevation of the left lid upon closure of the right eye, and instant return of ptosis upon opening the right eye.
3. Partial elevation of the left lid upon opening of mouth, extreme elevation upon added protrusion of tongue.
4. Failure of left superior rectus to draw the eye up synchronously with the elevation of the deficient lid.

Especially marked was this when the right eye was also open,—the lower edge of the left cornea being about 3 mm. below that of the right eye.

5. Irregular movements of the eyeball; an absence of regularity in the actions of the extrinsic muscles of the eye as associated with those of the fellow eye.

These conditions would indicate a preference of the psychical impulse to travel from the brain to the third nerve center of the left side (thus raising the right lid), a deficient connection between the third nerve centers or fibers with each other (producing unsymmetrical action), and, lastly, it would indicate an abnormal connection between the centers of the fifth nerve and the third nerve center on the right side of brain (causing elevation of left lid with the protrusion of the tongue).

The improvement which this patient made proves that the connecting fibers of the third nerve were merely deficient and not absent.

George N., aged 6 years, male, schoolboy, entered my clinic at St. Christopher's Hospital Dispensary on April 27, 1900. Family history is entirely negative. Father and mother living, well; have 3 other children, all of whom are healthy in every respect. Mother says she had a severe fright, while pregnant at 6 months with the child, on account of false report of her husband's death. The child was born at term

¹Swanzy, "Diseases of the Eye," last edition.

with the assistance of a midwife and without any complication. The mother noticed that the left side of face was thin and poorly developed, compared with the right side, and that there was an absolute ptosis of the left lid. The child could not lift the lid at any time apparently for several years. The baby was very nervous and could not walk until he was more than two years old. He has gradually been improving in general health since then without special medical attention. He has never had any sickness other than measles and chickenpox 4 years ago.

The present condition is as follows: There is a marked frown constantly present on the forehead; complete ptosis of the upper lid of the left eye—which is instantly removed by covering the right eye, and just as quickly returns when the eye is uncovered. When the mouth is opened the lid is three-fourths elevated; the protrusion of the tongue causes an extreme elevation, lasting about one minute, when the ptosis gradually returns. Upon each and every fresh protrusion of the tongue, the lid is instantly elevated. The ptosis becomes extreme when fixation is attempted and the mouth is closed. When the right eye is not converging, there is usually a small margin of the sclera visible between the left lid upon voluntary effort at elevation. Upon monocular fixation the ocular movements of the right eye are good in all directions, while those of the left eye are somewhat restricted upwards and inwards, otherwise normal. When the left lid is forcibly elevated—upon binocular fixation—O. S. turns down and out. Upon increased convergence of O. D. the left eye diverges markedly. There seems to be but little correlation in the ocular movements of the eyes. The pupils of each eye are 2.5 mm. in diameter, and the irides respond equally and freely to light, accommodation and convergence. There are no apparent associated movements of the pupil. Abduction, adduction or movements of the head do not affect the ptosis. There is but a slight asymmetry of the face at the present time, the left side being somewhat smaller than its fellow. The patient has a high arched palate, hypertrophied tonsils, especially on the left side. He can breathe easily through nostrils. Ophthalmoscopically, without use of a mydriatic the following condition was revealed:

Right eye. Pupil oval, long axis 90° , media clear. Disc oval, 7×8 , long axis at 60° , there is a faint chorioidal ring all around disc, excentric excavation outside, vessels at the long axis of the disc being best seen with $+2$ D.

Left eye. Pupil oval, long axis at 90° , media clear. Disc oval, 7×8 long, axis 100° , reddish grey in tint, chorioidal ring all around; there is a marked absorption of retinal epithelium throughout the visible eye-ground. The veins are rather full. Vessels at the long axis of disc are best seen with $+2$ D.

It was impossible to procure fields of vision or the muscle-balance, on account of the patient's youth and unreliability of answers.

The treatment adopted was the administration of strychnin sulfate $\frac{1}{16}$ grain 3 times daily, and the occlusion of the right eye for a portion of each day.

July 30, 1900. The patient is able to keep the left lid elevated voluntarily, and does so about half the time. Upon close fixation, however, after the lapse of 1 or 2 minutes, the left lid begins to droop, the eyeball following it in its course so that the lower edge of the left cornea is 4 mm. below that of the right cornea. After a momentary closing, the will-power is again applied, resulting in a sudden, almost spasmodic, extreme elevation of the left lid. In this the eye follows, but incompletely, so that a small area of about 2 mm. of sclera is seen above the cornea and below the upper lid.

Fixation of objects at one or more meters leaves the eyes in an apparently normal position. Close fixation still results in convergence of the right eye and divergence of the left eye.

The condition is, however, markedly better than when first seen by me.

In conclusion, I wish to call attention to the following:

1. To the marked improvement in the congenital lesion—complete ptosis—so that patient can voluntarily raise the lid and keep it open most of the time.

2. To the theory that there are, in most persons, con-

necting fibers between the fifth and third nerves. Many people in apparently normal health, when protruding the tongue or opening the mouth very wide, will also increase the palpebral fissure by extremely elevating the lids. In the pathological condition of congenital ptosis, I would suggest the probability of an excessive development of these weak connecting fibers, and an equally great lack of development in the proper third nerve fibers nominally supplying the parts involved.

That these fibers were present in this case is evidenced by the improvement which followed immediately upon the exercise of the deficient lid, by compelling the patient to keep the eye open as long as possible by occluding the fellow-eye. At first, the left eyelid tired very quickly, but gradually the exercise could be continued several hours. At the present time he can voluntarily lift the deficient lid and keep the eye open a great proportion of the time, even with the right eye exposed.

NATIONAL VOLUNTEER EMERGENCY SERVICE MEDICAL CORPS; ITS OBJECTS, SCOPE AND IMPORTANCE.¹

By J. ADELPHI GOTTLIEB, M.A., M.D., LL.D.,

of New York City.

Commandant Director General Nat. Vol. Emerg. Serv. Med. Corps; Associate of the Military Service Institution of the United States; Member of the New York County Medical Society and Ass'n; Medical Ass'n Greater City N. Y.; Fellow New York State Medical Ass'n; American Med. Ass'n, etc.

PUBLIC health and welfare has become of late years one of the most important elements of modern civilization. It is a subject in which all mankind has an interest. The suggestions embodied in this essay, for an institution which is to protect the health, life, and limb of the public is offered as a contribution to a great cause; and the writer sincerely trusts and hopes that it will have the desired influence, by promoting the welfare and comfort of the community.

Hitherto, the great subject of rendering aid at catastrophes of national importance, or in the field in time of war, belonged almost exclusively to private civic aid societies. We all appreciate the grand and noble work accomplished by the various "Red Cross" societies the world over; and that they have served as a valuable auxiliary is an undisputed fact. More, their services were absolutely required and needed, but the sphere of usefulness of such private societies is a matter of the past. True, they have been the incentive, but the time has arrived when they must give way to the improved methods of this enlightened century.

By the subjoined citations we are characteristically reminded of the necessity of a thoroughly trained and disciplined corps, with all the advantages of regular drills, routine emergency work, and the resulting comradeship and *esprit de corps* due to the social intercourse of its members, with a staff corps enrolled from among the foremost men of the nation. From such a body the Government could draw material when in need of same—a quasi training school, or "waiting list," as it were.

The following excerpt from an official report is to the point, and proves the need of such a corps:

"The difficult and delicate questions connected with philanthropic assistance outside the permanent military organization are regulated thus: Representatives of Aid Societies must place at the disposal of the commandant their staffs of attendants and all supplies brought by them, for dis-

¹ Presented to the Section of State Medicine, American Medical Association, at the meeting held at Atlantic City June 5, 6, 7, 1900.

tribution to hospitals, etc., and societies have no power to remove or distribute their members or supplies, and no civilian is allowed to visit any hospital except on pass especially granted. This regulation will be appreciated by officers who are cognizant of the wasteful and often demoralizing prodigality of Aid Societies, and of incompetent intrusion that, intermingled with valuable aid, embarrasses active military service. Any popular war will find the volunteer army that must prosecute it, flooded from the rear with patriotic gifts and overrun with enthusiastic helpers."

The foregoing needs no comment, as it is a clear statement of conditions existing in the past, and to date, the world over. This almost tolerable condition of affairs is further augmented by a recent dangerous and outrageous phase of reckless manner in which these private societies are conducted, and the integrity of the personnel which compose some of them. The misuse of this plausible disguise, suggests the greatest care to be observed in endorsing private "Red Cross" movements, unless they be under absolute control of particularly well-known and reliable auspices. The recent episode brought to public attention, and on which an editorial in the *New York Medical Journal*, vol. lxxi, No. 17, for April 18, 1900, comments with deserved severity on the treason to the Geneva Cross of a so-called hospital corps that went from this country to the Transvaal. (The editorial is of such merit as to deserve being quoted in its entirety):

TREACHERY TO THE RED CROSS CAUSE.

An incident has recently occurred in relation to the South African War which is discreditable beyond expression; if that were all, however, it would not be worth our while to comment on it, but when we add that it seriously jeopardizes the future status of those grandly humane principles which form the keystone of Red Cross work, and are one of the greatest glories of the present age, we are giving good reason for the exclamation in which the perpetrators of this dastardly outrage must ever be held by all right-thinking people. The outrage to which we refer is the action of the so-called "Chicago Ambulance Corps," the members of which, leaving these shores under the auspices of the Red Cross, ostensibly as an organization to tend the wounded Boers in the Transvaal, on their arrival at Pretoria almost to a man tore off their Red Cross Badges and accepted the arms offered them by the Boers, to take part as combatants in the struggle. This action has, it would appear, been followed by other so-called ambulance corps in the Transvaal.

The whole value of the Red Cross organization depends upon its being always above suspicion of any partisan motives. It is only by implicit and unshaken faith on the part of all who may chance to be belligerents that no hostile use will ever be made by any power of the neutrality, the immunity, and freedom of movement and action accorded to the Red Cross insignia, that these privileges, so essential to carrying out its glorious object, viz., the mitigation of the inevitable suffering of warfare, can continue to exist. The deadliest blow that has ever been struck at the laudable work of the Geneva Convention has been delivered by this so-called Chicago Ambulance Corps. It was cowardly and treacherous, and we sincerely hope that every one who has participated in it will meet the fate in Africa which he richly deserves. The isolated instances of misuse of the Red Cross flags, of firing on ambulances, and of firing from ambulances are trivial in comparison with this in their far-reaching import. Such acts must first be clearly proved to have been intentional, which in the vast majority of cases on either side we refuse to believe them to be; and, when, unfortunately, some individual instance is shown to be not accidental, but due to design, even then we must make allowance for the fact that no commander of a large army can control omnipotently the action of every individual in it any more than the most civilized community can entirely prevent the commission of crime. All that can be done is to visit an offence with condign punishment of sufficient severity to act as a deterrent to the great multitude.

But if there be room for suspicion that duly accredited

Red Cross emissaries may not be really philanthropists at all, but foes in disguise, and cowardly and treacherous ones at that, then the whole foundation of the beneficent Red Cross Institution will have been shaken, and military commanders will find it a matter of wisdom to "ward off" all such bodies from the theater of war, lest they should prove wolves in sheep's clothing. Thus all the great benefits of the humane spirit of the age, essaying to reduce the, in any case, appalling suffering of warfare to a minimum, a spirit never probably displayed to such great advantage as in the South African war, will be dissipated, and warfare will be conducted as aforesaid with the barbaric savagery from which it has in the passing century so largely emerged.

The band of unscrupulous marauders to whom we have referred, came near, we understand, owing to their swash-buckling behavior and other suspicious circumstances, being stopped at Lorenzo Marques from proceeding further, but the circumstances which finally turned the scale in their favor and secured a letter from Miss Clara Barton, testifying to her personal acquaintance with their identity and objects. It is painfully evident that Miss Barton, whose name commands respect everywhere, has been sadly duped in the matter, and we sympathize earnestly with her in the mortification which she is now evidently enduring at the treatment meted out to her by her protégés. We trust that the lesson thus received will prevent any further countenancing of independent and irresponsible bodies for Red Cross work, and that only regularly enrolled Red Cross members, of some standing, will, in the future, have their services in any way recognized.

We think that all questions of the merits of this or any other war side, any belligerent capturing such treacherous persons would be perfectly justified in not extending to them the privileges of prisoners of war, but dealing summarily with them. Nay, more. Such wholesome action would prove clearly that the neutrality of the Red Cross must and shall be respected, that it may continue unmolested to discharge its glorious functions.

The preceding argues forcibly for the necessity of a recognized, disciplined, strictly medico-military corps whose members are obliged to take an oath of fealty and are amenable to the most stringent military laws and discipline. Therefore in this onward march of natural events we must look forward to a regularly organized institution in accord with the strides and progress of the twentieth century. The subject which I present to your attention is an attempt to meet this latest and important phase of social economy.

That a growing attention to the subject of protecting the health of the people is being manifest all over the world, cannot be denied; for today the most learned and distinguished members of the scientific world are engrossed in the problem of preservation of public health; and the people and press, who are rarely slow to comprehend matters which it is to their advantage to know, are beginning to appreciate the necessity for a regularly established volunteer emergency corps and the benefits consequent thereto. Every good citizen takes a just pride and deep interest in the safety and prosperity of his country, and his patriotism bears a direct ratio to the degree of attention and protection he is to receive in time of need.

Within the past few years we have all become painfully cognizant of the numerous local and national disasters, in which, in almost every instance, the hands of both civic and military authorities have been tied for various reasons, such as—time required for the course of official sanction, unavailable funds, inability of procuring immediate equipment, inefficient or lack of expert service, etc. I need but mention the yellow fever and smallpox outbreaks in various parts of the United States (Marine-Hospital Service alone reported 4,286 cases of yellow fever), catastrophies occasioned by the floods, hurricanes, cyclones in various sections of

the country; the tornado in Northern Missouri, etc., in which multitudes were killed, injured, or rendered homeless; the West Dunellen, Redding, Hudson River and Santa Fe Railroad accidents; the many conflagrations; and, lastly, the breaking of a platform during a public function at St. Augustine, Fla., in which 200 persons were injured, not forgetting the ravages of the plague in the East, which at this writing reports from Bombay mention 12,323 deaths recorded from the plague from November 19, 1899, to February 17, 1900, a short period of but three months; and over 6,000 in other districts in India. In the Philippine Islands 100 cases were reported between January 20 and February 15 of this year. It is unnecessary to further summarize the appalling disasters and catastrophies. The safeguards for epidemics must be attentively watched and provision made so as to be able to amply cope with any unforeseen surprises; particularly with this state of activity in our newly acquired channels of infection—the colonial possessions.

The formation of a completely equipped, trained, and drilled volunteer emergency service medical corps is a natural consequence and is inevitable. Such an institution would at once inspire public confidence, allay and dispel all fear and anxiety from the minds of the people, by being ready to serve the community at a moment's notice. This advanced period demands such an energetic and efficient organization as the following excerpt from the constitution of the National Volunteer Emergency Service Medical Corps will prove:

"Its objects shall be to render medical or other aid and relief to the community in event of pestilence, catastrophe, war, etc., by maintaining an equipped, trained, and drilled service corps, to anticipate, prepare, and execute sanitary measures which will insure the health and safety of life and limb of the people. To render aid to injured, transport sick and injured to place of succor, to provide food, shelter, clothing or medical relief and medicines to the victims of calamities as exigencies may require. To encourage the reading and discussion of papers on subjects pertaining to sanitary, medical, medico-military and public health matters; and to place equipments and service at the disposal of civic and military authorities of National or State Government subject to requisition on call.

"There shall be an Advisory Council, whose duty it shall be to act in an advisory capacity on all matters concerning the good and welfare of the organization, guard its interests, and who shall suggest ways and means for improvement or advancement of the objects of the corps. Of which the following shall be ex-officio members: the President of the United States, Vice-President, Secretaries of State, Treasury, War, Navy, Interior, Attorney and Postmaster-Generals, the Judges of the Supreme Court of United States, the General commanding the Army, and Generals commanding the military departments of the United States, Admirals of the Navy, Surgeon Generals of the Army, Navy, and Marine-Hospital Service, the Governors of the several Commonwealths of the Union, the president and chief health officer of each State Board of Health, the president of each duly incorporated and regularly accredited National and State Medical Society. All of whom shall be ex-officio members while holding their respective official position, and such eminent and distinguished persons whose sentiment is in accord with the objects of the corps and whose wise counsel is beneficial, may be elected by the Executive Board of Administration permanent members."

PERSONNEL.

CLASS A.—CIVILIANS.

The corps to be composed of civilians from the various walks in life (bankers, merchants, artisans, tradesmen, clerks, etc.) who enrol for a period of 5 years as privates of the Hospital Corps and take an oath of fealty and allegiance to the Constitution of the United States, constitution of State and National Government to nonpartisan neutral aid

in emergency as noncombatants, in accord with the articles of the Geneva Convention; and to be governed by the military code and regulations of the corps; they are required to attend weekly or monthly drills, at least 8 in the year (one evening a week or month, optional with the command) for instruction in first aid to injured, common means employed for the urgent relief of the sick or injured; individual and camp hygiene; matters pertaining to epidemics, catastrophies; transportation of sick or injured; litter drill and instruction in military evolution, the senior medical officer of a detachment being responsible for the theoretical and practical instruction of officers, noncommissioned officers and privates of the hospital corps, who will institute a regular school of instruction, and the senior commandant of field service will instruct in military drill and custom.

From the privates of the hospital corps are appointed (after election by their colleagues and examination for their fitness by the proper officers), the commissioned and non-commissioned officers, such as medical officers, adjutants, quartermasters, chaplains, wardmasters, armorers, trumpeters, ambulance drivers, blacksmiths, carpenters, etc.

CLASS B.—MEDICAL STUDENTS.

Medical students who by reason of special education and intended devotion to the treatment of the sick are enrolled on the list of medical cadets and are assigned to a squad of litter bearers for field work, as lance corporal, and are next in line for promotion as acting hospital stewards.

CLASS C.—TRAINED NURSES.

The nursing corps consists of female trained nurses (hospital graduates), who enrol for a period of 4 years and who receive special professional instructions in the routine work of military hospitals, care of patients in special cases, sunstroke, suffocation from smoke, exhaustion, conduct and care of infectious and contagious diseases, epidemics, quarantine, etc., and who are assigned to duty at shelters, field hospitals, lazarettos, field infirmaries, receiving depots, etc. From this corps could also be available at a moment's notice extra nurses for public institutions in events of immediate necessity, such as sudden accidents or epidemic, where the regular resident staff of the institution is overworked or insufficient.

CLASS D.—GRADUATE PHARMACISTS.

Regularly licensed pharmacists who enrol as privates of the hospital corps are appointed (after examination) as hospital stewards and apothecaries to hospitals, shelters, lazarettos, field-infirmaries, etc.

SERVICE STAFF CORPS.

Consists of qualified physicians appointed from civil life, after medico-professional and military examination; and of retired or honorably discharged surgeons who have been in the service of the Army, Navy, Marine-Hospital Service, National Guard or State Militia who are assigned to duty and rank respectively:

RANK.	CAPACITY.
Surgeon-Lieutenant int.	Acting Assistant Surgeon.
Surgeon-Lieutenant (1st).	Assistant Surgeon.
Surgeon-Captain.	Passed Assistant Surgeon (Senior).
Surgeon-Major.	Surgeon.
Surgeon Lieut.-Colonel.	Surgeon (Chief of Hospital).
Surgeon-Colonel	Surgeon " "
Surgeon-Capt.-General.	Medical Director.
Surgeon-Major-General.	Commandant Director-General.

ADMINISTRATIVE STAFF CORPS.

Surgeon-Major General, Commandant Director-General.	
Captain-General.	Adjutant-General.
" "	Judge-Advocate General.
" "	Quartermaster-General.
" "	Commissary of Subs.-General.
" "	Purveyor General.
" "	Paymaster General.
" "	Inspector-General.
" "	Chief Sanitary Engineer.

Who are selected from civil life or from ex Army, Navy or National Guard and Military officers by virtue of their recognized integrity and ability, by being specially qualified for the departments to which branch of service they are assigned.

HOSPITAL AND AMBULANCE CORPS.

In order to facilitate the rendering of prompt and efficient service and to insure the proper grade of authority, discipline and regular defined duties, and permit organization on a minimum basis, the corps is divided into a series of working units, and designated according to the strength of each command, thus:

A squad—four privates of the hospital corps, one medical cadet, one nurse, one wall tent, two stretchers, four cots, the unit. A detail, consisting of three squads; a company, consisting of three details; a platoon, consisting of two companies; a battalion, consisting of two platoons; a division, consisting of two battalions; a department, consisting of two divisions. And the consequent complement of extra officers, etc., as the command is augmented.

A DETAIL.

Composed of three squads; 12 litter bearers, 3 medical cadets, etc., 3 nurses, 3 wall tents, 6 litters, 12 cots. Plus—

Additional allowance. { 2 acting hospital stewards,
1 acting assistant surgeon lieutenant,
1 assistant surgeon 1st lieutenant,
1 adjutant sergeant-major,
1 trumpeter,
1 large wall tent, 1 ambulance, 6 litters, 3 cots.

COMPANY.

Composed of three details; 36 litter bearers, 9 medical cadets; 9 nurses; 6 acting hospital stewards, 3 acting assistant surgeons, 3 assistant surgeons, 3 adjutant-sergeant-majors; 3 trumpeters, 3 large and 9 small wall tents, 36 litters, 45 cots, and 3 ambulances. Plus—

Additional allowance. { 3 assistant surgeon-captains,
1 surgeon-major,
1 commandant of ambulance service lieutenant,
1 adjutant lieutenant,
1 quartermaster-lieutenant,
1 commissary of subsistence lieutenant,
1 paymaster-lieutenant,
1 chaplain (no military rank),
1 sergeant ward master-armorers, 1 trumpeter,
1 cook, 4 artificers, 4 teamsters, 1 receiving depot tent, 1 ambulance, 1 material and supply wagon, 1 transport wagon, 4 litters, 5 cots.

PLATOON:

Composed of two companies, 72 litter bearers, 18 medical cadets, 18 nurses, 12 acting hospital stewards, 6 acting assistant surgeon-lieutenants, 6 assistant surgeon 1st-lieutenants, 6 assistant surgeon-captains, 2 surgeon majors, 2 lieutenants commanding ambulance service, 8 adjutant lieutenants, 2 chaplains, 2 quartermaster-lieutenants, 2 commissary lieutenants, 2 paymaster-lieutenants, 2 sergeant ward master-armorers, 8 trumpeters, 2 cooks, 8 artificers, 8 teamsters, 6 large wall tents and 18 small, 80 litters, 100 cots, 2 receiving depot tents, 8 ambulances, 2 material and supply wagons, 2 transport wagons. Plus—

Additional allowance. { 8 surgeon-majors,
1 surgeon lieutenant-colonel,
1 commandr. of ambul. serv. captain,
1 adjutant
1 quartermaster
1 commissary of subsistence
1 paymaster
1 chaplain,
1 sergeant ward master-armorers, 2 trumpeters, (one a corporal),
2 artificers, 1 cook, 4 teamsters, 1 field-infirmiry, 4 ambulances, 1 material and supply wagon, 1 transport, 1 baggage wagon, 20 litters and 50 cots.

BATTALION.

Composed of two platoons, 144 litter bearers, 36 medical cadets, 36 nurses, 24 acting hospital stewards, 12 hospital stewards, 12 acting assistant surgeon-lieutenants, 12 assistant surgeon 1st-lieutenants, 12 assistant surgeon-captains, 20 surgeon-majors, 2 surgeon lieutenant-colonels, 6 commanders ambulance service, 18 adjutants, 6 quartermasters, 6 commissaries, 6 paymasters, 6 chaplains, 6 ward master-

armorers, 20 trumpeters, 6 cooks, 20 artificers, 24 teamsters, 36 small and 12 large wall tents, 200 litters, 300 cots, 4 receiving depots, 21 ambulances, 6 material and supply wagons, 6 transports, 2 baggage wagons, 2 field infirmaries. Plus—

Additional allowance. { 2 surgeon lieutenant-colonels,
1 surgeon-colonel,
1 commandr. ambul. serv. major,
1 adjutant
1 quartermaster
1 commissary of subsistence
1 paymaster,
1 judge advocate,
1 sanitary-engineer,
1 inspector,
1 chaplain, 1 ward master-armorers, 2 trumpeters (sergeant), 4 artificers, 1 cook, 4 teamsters, 1 lazaretto, 25 litters, 75 cots, 3 ambulances, 1 material and supply wagon, 2 transports, 1 baggage wagon.

DIVISION.

Composed of two battalions, 288 litter bearers, 72 medical cadets, 72 nurses, 48 acting hospital stewards, 24 hospital stewards, 24 acting assistant surgeon-lieutenants, 24 assistant surgeon 1st-lieutenants, 24 assistant surgeon captains, 40 surgeon-majors, 6 surgeon lieutenant-colonels, 2 surgeon-colonels, 14 commanders ambulance service, 38 adjutants, 14 quartermasters, 14 commissaries, 14 paymasters, 2 judge-advocates, 2 sanitary engineers, 2 inspectors, 14 chaplains, 14 ward master-armorers, 44 trumpeters, 48 artificers, 56 teamsters, 14 cooks, 72 small and 24 large wall tents, 450 litters, 750 cots, 8 receiving stations, 54 ambulances, 14 material and supply wagons, 16 transport and baggage wagons, 4 field-infirmaries, 2 lazarettos. Plus—

Additional allowance. { 1 surgeon-colonel.
1 assist. adjutant-general lieut.-colonel.
1 " quartermaster " "
1 " commissary " "
1 " judge-adv. " "
1 " purveyor " "
1 " paymaster " "
1 " inspector " "
1 sanitary engineer
1 com. of ambulance service
1 chaplain, 1 ward-master-armorers, 2 trumpeters (sergt.-major), 8 artificers, 8 teamsters, 15 cooks, 144 small, 48 large wall tents, 50 litters, 250 cots, 1 ambulance, 1 field hospital, 1 shelter camp equipment, 3 material and supply, 3 transport, and 2 baggage wagons.

DEPARTMENT:

Consists of two divisions, 576 litter bearers, 144 medical cadets, 144 nurses, 96 acting hospital stewards, 48 hospital stewards, 48 acting assistant surgeon-lieutenants, 48 acting-assistant surgeon lieutenants, 48 assistant-captains, 80 surgeon-majors, 16 surgeon lieutenant colonels, 6 surgeon-colonels, 30 commanders ambulance-service, 78 adjutants, 30 quartermasters, 30 commissaries, 30 paymasters, 6 judge-advocates, 2 purveyors, 6 inspectors, 6 sanitary engineers, 30 chaplains, 30 ward-master-armorers, 92 trumpeters, 112 artificers, 128 teamsters, 30 cooks, 144 small, 48 large wall tents, 500 litters, 1,000 cots, 16 receiving stations, 110 ambulances, 34 material and supplies, 38 transports, 16 baggage wagons, 8 field infirmaries, 4 lazarettos, 2 field hospitals, 2 shelter camp equipments. Plus—

Additional allowance. { 1 surgeon-captain-general medical director,
1 deputy adj. tant general colonel.
1 " quartermaster " "
1 " commissary " "
1 " judge-adv. " "
1 " purveyor " "
1 " paymaster " "
1 " inspector " "
1 " engineer-in chief " "
1 " com. ambul. service "
1 ward master-armorers; 3 trumpeters (principal musicians), 3 artificers, 2 teamsters, 1 cook, and such other personnel and equipments as may be found necessary.

The uniform is of "cadet gray" cloth, regular brass button blouse, trimmed with green and red, or green and gold, with proper marks for easy and quick identification.

Commissioned officers wear fly-front coat, trimmed with gold, silver, and green.

The uniforms are at once attractive, serviceable and entirely original, thus easily recognized and memorized as to what organization the wearer belongs.

Such a corps organized and equipped on the preceding military system, disciplined and specially trained, would be ready for any and every immediate emergency service, whether casualty, epidemic, riot, war, parade, or civic function (*at which casualties generally occur*).

With such an ambulance service detail—company, platoon, or battalion—permanently established and located in every city and town in the Union ready to render relief whenever and wherever required, and prepared to be called into requisition at a moment's notice to assist State health boards in the enforcement or execution of sanitary measures, or in the field at the call of civic or military authorities, would inspire the confidence of the people and assure the safety of the community.

Every loyal and public-spirited citizen should consider it a privilege to become a contributing member or annual subscriber of such organization, and the public no doubt would do their utmost toward securing such efficient corps. The vast field of usefulness for such complete body is patent, and needs no further comment, the actual necessity of which is so obvious as to hardly need more than mention to carry conviction to all minds, even such military authorities as are prejudiced against such organizations through their unfortunate and harassing experiences with undisciplined and incompetent private aid societies. It is equally logical to assume that public approbation and support would be proportionate to the actual and prospective benefits to be derived from such organization.

Some opposition might be encountered as to the acquirement of military titular designations. But all objections to that are overcome by the fact that the designations of military rank and title are based upon the nomenclature in use by various governments of the world, thus making the system universal, or rather, international. The corps being an independent military unit for itself, with clearly defined duties and scope of action, characteristic and original uniforms (gray color with green trimmings) which are easily recognized, and in no way conflicting with the appearance of the established Governmental forces extant. This corps would in no way interfere with the work and duties of existing regular military bodies or with National or State organizations, but rather, in case of emergency, encourage and cooperate with them. The clothing, therefore, of its officers with military rank is only for the purpose of giving grade of authority and distinction, which, it must be acquiesced, is absolutely essential and necessary to secure obedience, respect of inferiors, and to facilitate the proper discharge of designated duties. The further reasons for conducting the organization on a distinct military system are apparent, as will be seen, for instance, should the corps be required to take to the field in aid of the civic government in epidemics, etc., the duties required of the special purely military departments are obvious, as will be appreciated by a brief review:

Adjutant's Dep't.

Keeps the records and archives of the organization; its personnel, strength and location of commands; issues orders; attends to the clerical duties of the body.

Judge-Advocate Dep't.

Is the legal advisor of the organization, advises as to quarantine and military law; and is the department to which all questions as to the administration of justice are referred.

Quartermaster's Dep't.

Provides quarters and transportation for the corps, shelter for the victims of calamity; storage of supplies, equipments, etc.

Commissary Dep't.

Arranges and provides for the feeding of the corps when in the field; distributes and purchases food for the victims of catastrophies.

Purveyor's Dep't.

Acts as the expert purchasing agent of the organization, contracts for supplies, equipments, etc.

Engineer's Dep't.

Advisees as to laying out of camp and temporary settlements; erection of shelters, securing and purifying water; prepares topographical diagrams of the country; maps; telegraph and field signals, etc.

Paymaster's Dep't.

Has charge of the funds of the organization, its receipts and disbursements, collections, etc.

Inspector's Dep't.

Reports and examines into condition of commands; proficiency and discipline of personnel; condition of equipments, etc.

From the preceding brief epitome outline recital of the facts, there can be no question as to the efficiency and importance of such an ideal institution; such highly efficient public sanitary organization is a befitting monument to public spirit and progress of the century. Without entailing either upon National or State Government the expense of maintaining or equipping, being self-supporting from the revenue derived from subscribing members, no better avenue could be found where philanthropic people are more assured that their money is not misdirected, having individual voice in its disposition, which could not be given to a better cause than that of helping mankind in time of greatest need. Guarded by an advisory council composed of the leaders of the nation, the best disposition of its funds is assured.

With our vast wealth and tremendous population, public spirit, and our country the first in enterprise, which surpasses in energy and leads the world in manufactures, we should not hesitate in showing other nations our advanced ideas and American spirit for protecting and aiding our fellowmen.

The enthusiasm engendered by the recent wars and disasters has not altogether subsided, and the many trials and embarrassments encountered are still fresh in the public mind.

Thus the foregoing rational demonstration of this seemingly stupendous task, is simple enough indeed, if we call to our assistance the aid of that strong factor and moulder of public education, the ever alert public press, which in this advanced and enlightened century reaches the eye, ear, and heart of every loyal wellwisher of our glorious country.

Thus with the voice of the community in favor of this movement, the press of the land could grasp this opportunity to use its tremendous power and influence to disseminate broadcast the call of this movement in aid of public welfare—a magnificent organization, the admiration of the world, which would stand as a unique and perpetual monument to our American spirit and zeal for ages to come.

VOL. VI, No. 25

DECEMBER 22, 1900

\$3.00 PER ANNUM

Organized Defense of Physicians in Unjust Malpractice Suits is one of the most pressing duties of the profession. Such a union has existed in London for several years and has been of the greatest service in preventing blackmailing suits and injustice to honorable physicians, the number of cases having been greatly reduced from that of previous years by the mere deterrent effect of the fact that thoroughgoing defense would be insured to those unjustly assailed. In Minnesota such a union is in active and beneficent operation, limited to the State, and in Canada the plan is under discussion. The only American institution with which we are acquainted, and the territory of which is not limited, is the Physicians' Guarantee Company, of Fort Wayne, Indiana, which is commended by Dr. Reed, the president of the American Medical Association. We trust that organizations undertaking such work under the proper conditions will become popular with the profession, because it is a great wrong when a capable physician having done his duty is subjected to the expense of defending himself, and the wrong becomes infamous when in addition he may lose his case because of inadequate defense. Of course, the greatest care must be exercised by the companies in not defending real malpractice cases.

Intestinal Bacteria and Intestinal Poisons in the Brain as a Cause of Infantile Convulsions.—Intestinal disturbances have often been considered the cause of convulsions in children, but there has been very little direct proof that there was any real foundation for this belief, and the etiology of this condition has not been very satisfactorily explained. Johannes Seitz, of Zürich, in the *Correspondenz-Blatt für Schweizer Aerzte*, 1900, vol. 30, p. 138, reports interesting observations on this subject, together with seven cases in which he has been able to demonstrate intestinal bacteria as a cause of brain symptoms. In this paper he reports at length the case of an infant that had always suffered from gastrointestinal disturbance and constipation. After several attacks of convulsions death resulted and Seitz was able to cultivate from the cerebrospinal fluid of the ventricles of the brain *Bacillus coli communis* together with several other intestinal bacteria. For some time the strength of the little patient had enabled it to overcome this source of cerebral irri-

tation, though the symptoms of vomiting, unrest, and pain were present, but sudden death resulted from respiratory and cardiac paralysis. Seitz mentions several publications in which he has called attention to this subject previously, the earliest publication having appeared in the same journal as the present publication in 1895. In all he has observed 15 cases in which he believed there was evidence of this origin of the cerebral symptoms, and in seven cases bacteria from the intestine were directly demonstrated. In the other cases it is quite possible that the symptoms were caused not by bacteria directly but by bacterial poisons. The bacteria were discovered only after the most thorough examination and they were usually present in small numbers. Staphylococci, streptococci, and members of the colon group were most frequently found.

Although Seitz first published his observations so long ago as 1895, and has subsequently called attention to the subject in two other well known journals, his work does not seem to have attracted much attention or to have been confirmed by other observers. His report of this case is fully given and shows evidence of careful work. The observations are suggestive, and if confirmed, may be helpful in explaining several rather obscure conditions whose etiology has been thus far imperfectly understood.

Of the baleful possibilities of alcoholic indulgence medical men need no extraprofessional evidence. To it can be traced no small measure of crime, disease and death. The appeal of the commander-in-chief of the British forces in South Africa that the welcome of the troops returning to England "may not take the form of 'treating' the men to stimulants in public houses or in the streets and thus lead them into excesses which must tend to degrade those whom the nation delights to honor," is therefore both timely and judicious. There may be legitimate differences of opinion as to the physiologic activity and the therapeutic utility of alcohol, as to what constitutes temperate or moderate and what excessive indulgence, but none will deny that those who abstain are on the safe side and assume no risk.

The definition of the word "operation" would, at first, seem sufficiently clear, and yet, when rigidly scrutinized, it is by no means so. A recent medicolegal

case brought several errors and indistinctions to the attention, and upon collating and classifying the definitions given in a large number of lexicons we find noteworthy differences and mistakes. All but one or two incorporate one or more errors, and there is one that gathers and endorses all of the five following inaccuracies:

1. An operation is performed by an authorized surgeon or by a legalized practitioner of medicine. An instant's attention shows that an operation may be performed by a nonmedical person.

2. It is performed by one person upon another who is the patient. But, as we all know, an operation may be performed by and upon oneself.

3. It is performed by means of surgical instruments. Operations, however, are performed every day without instruments.

4. It is manual. But every surgeon knows of operations done without the use of the hands.

5. It is with the object of relieving disease or restoring health. And yet in cosmetic operations, in vaccination, in criminal abortion, and in malingering, the object is not the restoration of health.

In the presence of these criticisms almost the only definition that will undergo testing is the simple one that an operation is a *surgical act* (or *procedure*). The essence of the matter appears to be expressible by one word which no dictionary, so far as we know, has caught. The distinctive difference between all other therapeutic measures and surgical ones resides in the word *mechanic*. This is manifest in the etymology of the word *surgeon*,—*one who works with the hand*. But though a surgical act may be carried out by other means than the hands, the nature of the procedure is mechanic in contradistinction to other means essentially chemic or physiologic.

The Epidemic in England of Peripheral Neuritis Traced to Arsenical Contamination of Beer-making Materials.—The official report (see *British Medical Journal*, December 8, 1900) of Dr. James Niven, Medical Officer of Health for Manchester, to the Hospital Subcommittee of the town on the outbreak of the arsenical poison, states that about 1,000 cases have been notified by medical men, and about 700 have been sent to the union hospitals. Allowing about 300 cases for which no returns have been made, there have been at least 2,000 cases seen by the physicians of the district.

Dr. R. D. Cran, medical officer of health, third district, Salford Union (in explanation of the terrible dimensions which the epidemic has reached), remarks on the difficulty of diagnosis in the early cases. During the past few months a gradually increasing number of cases of peripheral neuritis came under his charge which he attributed to some poisonous substance in the beer, clearly not lead, but which he did not feel justified in stating to be arsenic, as no rash was visible in

any of the cases. For some months he had had patients coming to him with peculiar skin eruptions, but he did not link the two series of cases, and in none was there any marked sickness or diarrhea. The majority of these cases of peripheral neuritis occurred in persons in whom it was nearly impossible to distinguish between the almost uniform darkening of the skin due to arsenic and that due to dirt, without closest examination, preceded by vigorous application of soap and water. It was only toward the later periods of the epidemic that cases began to emerge from the typical alcoholic type, with loss of memory and the peculiar waking dream-like state.

Although the cases of multiple neuritis have been less numerous in Liverpool than in Manchester, there has been a decided increase, and the symptoms correspond with those of beriberi, and it is remarkable that in all cardiac enlargement with a marked increase in the pulse was present. An investigation of the urine by Dr. John Hill Abram and Dr. Nathan Raw showed the presence of arsenic. Upwards of 1,100 barrels of beer have been emptied down the sewers.

In Heywood, Lancashire, in the last 6 months, 200 or 300 people have suffered from peripheral neuritis. Early in June a number of cases claimed the attention of the medical officer, and as close inquiry revealed that the sufferers invariably took beer or stout, an inspection was made of the brewery vats and pipes. Not only the heavy drinker has suffered, but those who took only from 1 to 2 pints daily. As soon as Dr. Reynolds' discovery was known, samples of beer and stout were analyzed and arsenic was found in some of the samples. He finds it difficult to believe that 0.04 gr. of arsenic per gallon could produce such serious symptoms in persons taking only a pint a day.

At Bacups the case of child, aged 2, is reported by Dr. John Brown. Her father keeps a public house and she was accustomed to get little supps of beer from the customers.

In 4 distinct cases of peripheral neuritis he examined the beer and found arsenic present, in some cases in dangerous quantities. Out of 14 different samples 12 showed distinct evidence of arsenic.

At Darlaston, South Staffordshire, 50 cases which came under the notice of Vincent J. Magrane were mostly ushered in with vomiting, diarrhea, severe abdominal pain, and urticaria, and all were among beer-drinkers of various classes.

William A. Newall and John R. Prytherch, of Chester, believe that some of the cases of peripheral neuritis are due to beriberi, and there seem to be no restrictions regarding the landing of sailors from ships affected with beriberi.

Pigmentation in the cases presenting the most typical symptoms of beriberi were very slight or absent, and in others it came on several weeks after admission to hospital where arsenic had not been prescribed nor

beer given. None of the cases presented inflammatory lesions of the skin.

Newall and Prytherch are of the opinion that the present epidemic is due to some other cause than the arsenical contamination of beer—inasmuch as the amount of arsenic found in the analyses, varying from 0.01 to 0.28 gr. per gallon, does not constitute a dangerous contamination—and they note also the general absence of diarrhea. They record the ingestion of 6 pints of beer daily by men in a district supplied by 5 different breweries without any peripheral neuritis. Of the cases under their notice some were in total abstainers.

The increase of insanity among soldiers in the tropics has been the theme of much exaggerated comment for political purposes by vicious newspapers, yet it may be equally wrong to deny that there has been any increase. The report of the Surgeon-General of the army shows that tropical service in Porto Rico in 1899 caused 3.76 cases per 1,000, while in the United States the rate was only 1.37. For the whole army the rate for the ten years prior to 1898 was 1.7, but in 1898 it rose to 1.8, and in 1899 to 1.78. These figures may denote a great increase in the number of cases in the army which saw service abroad, for they are based upon the whole army strength which in these two years contained at least 100,000 men who served but a very short time and that in the home camps, and those that did go abroad had short tours as a rule. It is also said that many cases recover during the sea voyage home, and the number of cases officially reported is less than half of those actually insane. It has also been said that the cases of less severe mental failure, particularly in the older men, have been appallingly numerous. As these cases never appear in the reports, it is quite likely that the real facts will never be known. On account of the large percentage of recoveries among the younger men, there has even been a disposition to deny that they have been insane.

The real truth seems to be midway between these two extremes. All the cases appear to be cerebral exhaustion due to tropical diseases or the climate or the worries of the campaign, and, according to the severity of the exhaustion, the symptoms vary from simple loss of mental vigor to depression, nostalgia or actual melancholia or even the dementia of a permanent senility. Only those in whom the exhaustion has passed the limit of recuperative power are incurable, and these are to be expected mostly among the neurotic and the aged. In the press notices of the report of the chief surgeon at Manila it is stated that the sick report is increasing and that there is no hope of a decrease, because the soldiers are becoming more and more exhausted instead of becoming acclimated.

The lesson to be drawn from the facts would seem to be, that the coming reorganization of the army should

be of such a character that officers and men could be sent home as soon as they show signs of exhaustion and that they should not be kept there until they are too far gone to recuperate. If the Philippines are to be retained it looks as though there would have to be a constant stream of fresh officers and men sent there to replace the exhausted.

Suggestions to Writers, No. 63. Concerning the Accent, the Retrocession of Accent, the Elision of Syllables, and the Shortening of Words.—In a preceding article was noticed the power of emphasis of a chosen word in a sentence to change the meaning of the sentence. In the same way the accentuation of different syllables in a word may be used to lay stress upon a chosen aspect. For instance in a metaphysical discussion one may contrast or bring out his meaning better by strong emphasis of the first syllable of *immateriality*, or of *materiality*. One may say, "this is a car'cinoma, that a sar'coma, that an en'chondroma," although usually one would accent the penult. Such usages, however, serve to make it clear that a freedom of location of the accent in a word like that of a word in a sentence is for the most part lost. When, or for what purpose, the accent in English was deprived of freedom and chained down to a certain syllable in each word, are questions probably beyond clear solution. In some languages, for example, the French, there is no accentuation of syllables as commonly pronounced, and other things render the accent impossible even when desired. But in English another extreme came about, of always demanding an accent somewhere and often rendering the least important of all syllables the accented one. The logical method of accentuation, if every word must have an accent, would have been to put the stress upon the root or stem, upon the syllable which was the heart of the word and conveyed the essential and primitively significant thought. Instead of that the old English language-makers seemed to clap it down by rule of thumb, or mechanically, regardless of primary, secondary, or tertiary importance, thus serving to take much of the freedom and life out of the tongue. At present, however, we are apparently unconsciously, but still effectively, taking back the liberty of which we were deprived, at least we are taking liberties with accentuation that are highly interesting. Among other tendencies observable is an escape from the obligation of accenting some syllable of every polysyllabic word—as if otherwise it would not be full-fledged and respectable. In many compounds as usually pronounced there is no accented syllable whatever, or it is only slightly accented, or there is an imperfect double accent, *e. g.*, *cerebrospinal*, *adenocarcinoma*, *arteriosclerosis*, etc.

The retrocession of the accented syllable in a word is the most noteworthy fact in this connection. To be entirely aristocratic nowadays a word must not show a

penultean accentuation,—that is too plebeian. We remember a revered professor who vainly protested against this new fangle by an especially powerful accent upon the penult in *revenue*, *somnolence*, *recognize*, etc. Once, doubtless, we should have said *formida'ble*, at a later time, *formid'able*, while today the accent is placed on the first syllable. *Par-e'-sis* was once common; it is now *par'-e-sis*. And it is the same with thousands of words, in which the tendency is discernible toward a retrocession of the accent to the antepenult and even to syllables preceding that. For purposes of contrast we may even throw it back to the fifth, sixth, or seventh syllable, as in *homogeneity*, *heterogeneity*, *materiality*, *immateriality*, etc., etc. In some long compounds it may be a dozen or two stations before the end of the word. Now what is the result, the subtle logic hidden in this retrocession of the English accent? We suspect the same wisdom will be found, more unconscious, perhaps, but still a prerequisite of the evolutionary mechanism, in the merciless placing of the accent somewhere. Both facts indicate a husbanding of force, a comparative indifference or neglect of relatively unimportant syllables. In thousands of words we have elided a useless letter, although we still write *infra-abdominal*, *interrelation*, etc. We might wisely write *infrabdominal*, *interclation*, etc. This need and determination to shortcut and condense has served to make English the most concise of all languages, and the American has vowed to speed the process at double quick. How long will it be before the best dictionaries must regretfully and cynically chronicle *phone* without an apostrophe, and *wire* without quotation-marks? Willynilly, the conservative Englishman must henceforth *trek* into new etymologic lands and *outspan* where old linguistic customs must be renounced. A boorish philology may intolerably trouble a very aristocratic conqueror and may, as has often happened in the past, supremely dominate him—philologically! "We must educate our masters," is one method of concealing from ourselves that we have been defeated, and that "our masters" are right. It seems to us that the retrocession of the accent is simply one way of condensation by emphasizing one syllable toward or at the beginning of a word and belittling the rest, in many cases hustling them out of sight, in others utterly cutting off the useless tail. The more the accent is shoved toward the beginning of a word the less, when quickly spoken, one hears about all the syllables that follow after, until some are half-ignored, fused, or even lopped off entirely. The etymologic, perfectly proper three-syllabled *thyroid*, *choreoid*—who ever pronounces them except with two syllables? After we have said *for'midable* for a few years the *a* will be pronounced even less than it is now. After many generations of useless iteration people grew tired of *scientific*, *publcal*, *domestical*, etc., and those who would so write them now would be laughed and sneered at by

people whose ancestors would have made merry at *scientific*, etc. We have all grown tired of *publically*, rightly holding *publicly* to be preferable. Sometime, likewise, we shall recognize that to adverbialize a thousand words we need not insert the *al* which we have cut off as adjectives, but can insert the *-ly* directly, as, *e. g.*, *allopathically*, *homeopathically*, *scientificly*. The retrocession of the accent will help us to do this and many other good things. In accentuation we have already traveled backward in *allopathy*, and in *homeopathy* to the antepenult, and it may be doubted if *al'lopathy* is not the more common and the better pronunciation. If so, *ho'meopathy* is inevitable. As no one would raise a finger in aid of *homeopathical* and *eclectical* and *osteopathical*, let us not be dogmatically and allopathically antipathic but homeopathically assent? If Hahnemann had applied the dogma *similia* to linguistics instead of to medicine, he would have been far more successful as a philologist than he has been as a therapist.

Mosquito Inoculations of Yellow Fever.—We are in receipt from the War Department of copies of the following telegrams received at the Surgeon-General's office from Major Reed with reference to his mosquito inoculations in yellow fever:

TELEGRAM.

COLUMBIA BARRACKS, December 15, 1900.

SURGEON-GENERAL, Washington:

Experimental station established November 20; 3 cases already; diagnosis in 2 confirmed by Guitéras, Finley, Albertini, and Gorgas; theory conclusively proved.

(Signed)

REED.

TELEGRAM.

COLUMBIA BARRACKS, Cuba, December 16, 1900.

SURGEON-GENERAL, Washington:

Four cases all within period of incubation, diagnosis confirmed in each case by Guitéras and others; inoculation successful in 80%.

(Signed)

REED.

Encysted Perilurethral Growth.—Huger (*Maryland Medical Journal*, October, 1900) gives the history of a man of 70, who when young had several attacks of gonorrhea and in recent years had several times passed gravel from the bladder. While voiding urine he felt a hard body passing from the bladder along the urethra. It stopped suddenly with some pain and a blocking of the urine. No blood was passed. Soon the bladder became distended and there was great desire to urinate. A rubber and then a silver catheter failed to dislodge the foreign body. The patient reported that subsequently he passed a gravel, but was still unable to pass urine. Under local anesthesia an incision was made into the urethra, where a hard body could still be felt. The cut revealed a collection of gravel in the aggregate the size of a buckshot in the periurethral tissue. The mass was completely cut off from the urethra, but produced a bulging into the urethra sufficient to stop for a time the gravel which was passing. The author is of opinion that there had existed a stricture, and the pathologic condition posterior to this had led to the opening of several ducts into which the small gravel collected, granulations and new-formed tissue encasing them. The retention of the urine after the passing of the gravel is explained by an enlarged prostate and the condition of the bladder. [A.B.C.]

Reviews.

Studies in the Psychology of Sex. The Evolution of Modesty; The Phenomena of Sexual Periodicity; Auto-Erotism. By HAVELOCK ELLIS. Pages xii, 275. Sold only to Physicians and Lawyers. Philadelphia: F. A. Davis Company, Publishers. Extra Cloth, \$2.00, net.

The title of this volume expresses its general object, which is not, we believe, to feed a prurient and morbid taste under the guise of medical science, but to study in a serious manner the problems chosen. Many will doubtless disagree with the conclusions of the author, but those interested will at least find in the book a valuable contribution toward the elucidation of many obscure questions.

Diseases of the Heart, Bloodvessels, Lymphatics, Blood, and Ductless Glands. A wall chart. Published by M. J. Breitenbach Company, New York.

We are glad to see that pharmaceutical manufacturers are adopting methods of advertising more in consonance with professional and scientific standards. The waste of money, the tactlessness, and utter incongruity of much of the past advertising addressed to the medical profession have not been proofs of soundest judgment or of the best professional spirit. For these reasons we are pleased to note such an excellent attempt to epitomize the knowledge of the subjects and diseases presented by this wall chart. There is nothing said as to treatment, and, so far as we can see, the pathology and symptomatology are correct. We are also pleased to note American spelling.

Masters of Medicine: Thomas Sydenham. By JOSEPH FRANK PAYNE, M.D., Oxon., Fellow and Harveian Librarian of the Royal College of Physicians, Late Fellow of Magdalen College, Oxford. New York: Longmans, Green & Co.

Physicians will welcome this latest addition to the famous series of Masters of Medicine, issued in such excellent style from the press of Longmans, Green & Co. Considering that the constant complaint of all biographers of Sydenham has been the paucity of material, the present biographer must be congratulated upon the industry that has enabled him to produce the comprehensive volume which so systematizes and adds to the knowledge of this great man. Many of the facts have been obtained only through long and painstaking research through old records, and the volume throughout is compiled from original records, whether previously quoted or not. The indexing and bibliography of the volume is most excellent, and the literary style is beyond cavil.

A Manual of Medicine. Edited by W. H. ALLCHIN, M.D., Senior Physician and Lecturer in Clinical Medicine, Westminster Hospital; Examiner in Medicine in the University of London, and to the Medical Department of the Royal Navy. Vol. I: General Diseases. Diseases Excited by Atmospheric Influences and the Infections. 8vo, pp 441. New York: The Macmillan Company, 1900. From John Wanamaker's. Price, \$2.00.

This manual is comparable to the systems with which we have in recent years been made familiar. The present volume, dealing with general diseases, is made up of articles written by 22 contributors, including the editor. The authors are principally well known Englishmen, distinguished for their original observations with regard to the subjects on which they write, and the articles, while compendious, bear a certain stamp of authoritativeness. The scope of the work is defined as consisting in "an account of the various forms of disease, more especially from the point of view of their clinical manifestations and treatment. The subjects of etiology and morbid anatomy are briefly summarized, and . . . the aim has been to present such a picture of the several maladies as will conform to the appearances detected

at the bedside, and to enable the observer rationally to administer such treatment as our art affords." The volume is of convenient size and clearly printed.

Anleitung zur Diagnose und Therapie der Kehlkopf-, Nasen- und Ohrenkrankheiten. By RICHARD KAYSER, M.D., Breslau, 1901. A Guide to the Diagnosis and Therapy of Laryngeal, Nasal, and Aural Diseases. Breslau: Richard Kayser, M.D., 1901.

This book is designed for the use of those who take a polielinic course and desire to inform themselves rapidly concerning the essentials of laryngology and otology.

Methods of examination are carefully described, and the portion of the book dealing with laryngoscopy in children is especially worthy of note. The book contains nothing that would prove of interest to a laryngologist or otologist, but simply places well-known facts in a shape to be rapidly learned by students. The therapeutic portion of the work is not likely to be recommended by teachers to their classes, as laryngologists differ so greatly in the details of nose, throat, and ear treatment, and each one likes to teach his own methods. Kayser relates his in such a general way that it is hard to see how his brief descriptions, lacking all detail, can be of use even to guide postgraduates in their studies. For instance, the entire subject of septal deformities is crowded into the space of a little over a page. An attempt has been made to assemble so many subjects in the 159 pages of the book that the author has succeeded in slighting all but a few of them in a remarkable manner. The book does not seem worthy of so able an author.

Diseases of the Nervous System. By H. OPPENHEIM, M.D., Professor at the University of Berlin. Authorized Translation by EDWARD E. MAYER, A.M., M.D., Pittsburg, Pa. First American from the Second Revised and Enlarged German Edition. J. B. Lippincott Co., 1900.

American neurologists will doubtless be pleased to have a translation of Oppenheim's work on diseases of the nervous system. The work itself does not impress us as being more acceptable than any of our best American and English books on the same subject; but we must reflect that in writing a conventional textbook an author is of necessity restricted in the execution of his plan. It is difficult for him to be widely original, because he must travel a beaten track, and do over again what many others have done before him. In the performance of this task the author has been successful, and has produced a book which is both valuable and interesting, and yet is not particularly noticeable for its individuality. We cannot, of course, attempt to criticize it in these columns, but must content ourselves and our readers with a general impression. The book is marked by thoroughness in its pathology, and by much more therapeutic zeal than is usually found in a German writer. In fact, the treatment is quite optimistic and given with a detail that is hardly surpassed in any textbook. With all this the book is written from the latitude and longitude of Germany. The work of American neurologists receives but scant notice, and nothing like justice. This is noteworthy, because the reverse is just the opposite of true; German writers being sought and quoted in this country with a zeal that is not always tempered with knowledge and judgment. Oppenheim's book, we should say, will be a satisfactory addition to our already long row of neurological textbooks, especially as its writer has already achieved an excellent reputation as a neurologist.

Malaria in Italy.—It is reported that Prof. Celli and others interested in eradicating malaria from Italy are framing measures to present to the Chamber, making punishable by law the neglect of landed proprietors and all employers of labor to provide, in malarial districts, every means of fighting the fever. Another measure provides for the government supplying quinin to the public at a little more than cost price.

Correspondence.

PRESERVATIVE EMBALMING FLUID.

By JOHN S. MILLER, A.M., M.D.,
of Denver, Col.

Demonstrator of Anatomy, Gross Medical College.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I HAVE used Professor Addinell Hewson's "preservative injection for the embalming of human bodies" for dissecting-room study, the formula of which was recently published in your journal. This preparation is all that Dr. Hewson claims for it. It is a most valuable aid and comfort to the anatomist. When one enters an anatomical room where this formula has been used, he is at once impressed by the absence of the foul odors commonly found. Another feature is the life-like appearance of the cadaver, the subject looking better, perhaps, than in life, and to the touch the tissues are soft and pliant. The same natural appearance persists throughout the dissection. The most delicate white nerve fibers can be traced to their termination. At first it was suggested that the escaping vapor from the formalin (a constituent part) would cause severe bronchial irritation in the dissector. This is not the case, as the vapor of formalin is rapidly dissipated by volatilization. The value of Hewson's solution can be fully appreciated by those anatomists who remember the old zinc chlorid solution which bleached the tissues and caused shrinking and hardening of same.

COINAGE OF NEW WORDS.

By JOSEPH DAVIDSON, M.D.,
of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN the issue of the JOURNAL of November 17, Dr. D. Riesman proposes the coinage of certain new words, to be incorporated into the English language, and incidentally contribute to the felicity of medical phrase. The ready adoption of these new words would, in my opinion, establish an undesirable precedent. It is true the English language lacks that quality for word-formation which is peculiar to the German language, but for this the superior wealth of its vocabulary is sufficient compensation. There does not seem to be any necessity for "apeioration" when we can render the meaning of *Verschlimmerung* by such words as *deterioration*, *aggravation*, *exacerbation*, and others, according to the sense in which it is employed, if indeed it must be rendered by a single word at all. There are many terse and sententious English words for which there are no equivalent single German words. In spite of its etymologic analogy, "Apeioration" (Ger. *Verschlimmerung*) would not be the exact antonym to *amelioration*, for which the German is rather *Linderung* than *Verbesserung*, while *Verbesserung* is *betterment*, *amendment*, etc., and *Besserung* is *improvement*. Not any less dispensable seems to me the newly-formed word "parvify" and "parvification," from the Latin *parvus*, *facere*, as opposed to *magnify* (from *magnus facere*) in preference to *minify* (from *minus facere*) for the German word *verkleinern*, which may also be variously translated as *be-little*, *disparage*, *diminish*, *decrease*, etc., according to its meaning.

Why, after all, should the German language be made the standard for the English language? Therefore, why not "draw upon the English language as long as it can stand the strain?"

ARE DOCTORS' NAMES WORTH MENTIONING?

By JAMES H. MCBRIDE, M.D.,
of Pasadena, Cal.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

MEDICAL journals seem to be adopting, or have adopted, the practice of referring in their abstracts to authors of medical articles by their surnames, omitting their initials. If an author is to be properly identified his initials should be given. I saw lately in a medical journal that Sachs said so and so. Did this refer to Dr. B. Sachs of New York, or to some Dr. Sachs in Germany, or some other of the 11 of that name in America? The reader is entitled to know and he can only know when the name of the author, not half of it, is given.

There are 35 McBrides practising medicine in the United States. They are, of course, all generous and thoroughly good fellows and yet not one of them but would wish to have his name mentioned in full in a medical journal when mentioned at all. Think of some reviewer saying McBride says so and so, and thus scattering the credit that belongs to one into nine States and among 35 names. When I write a good thing, which, of course I rarely do, I wish to have credit for it; the very rarity of the feat makes me the more anxious that my work be properly credited.

Imagine writing Mitchell for Weir Mitchell, or DaCosta for J. M. DaCosta. There are other DaCostas and Mitchells who might do something worth mentioning. Think of their honors being swallowed up by those continental reputations in Philadelphia. The other DaCostas and Mitchells must have chilly sensations when they think of it.

Initials testify to the progress of the race; they were used to designate men as particular individuals when it came about that the individual was worth mentioning because he amounted to something.

Of all the minor possessions that man has gained during the toilsome centuries, there is none that confers upon him more of what is strictly an individual character than the little letters he puts before his surname. Not even his hairless body, nor his erect spine, nor the house he lives in, nor his bank account, nor his oratory, nor the books he writes, mark him off from his fellow men; but his initials do, and in this hurrying life he is at least entitled to the brief distinction of a name, one that will enable the world to identify him.

BIRTH OF AN ANENCEPHALIC MONSTER, FOLLOWED
TWO YEARS LATER BY ONE OF SPINABIFIDA
WITH CONGENITAL ABSENCE OF THE OCCIPUT
AND DOUBLE TALIPES VALGUS.By A. M. DAVIS, M.D.,
Pathologist to the Germantown Hospital.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

PATIENT J. R., aged 34 years; married at the age of 26; had the usual diseases of childhood, but was always otherwise healthy. All history of alcoholism or venereal disease absolutely denied by both parents. Her children were born as follows: First child—10 months 2 weeks after marriage—healthy; second child—17 months 2 weeks after first—healthy; third child—2 years 3 months after second—healthy; fourth child—2 years 1 month after third—healthy; fifth child—3 years after the fourth—healthy. These children are living at present and show normal development. Two years after the birth of the fifth child, a miscarriage occurred during the third month of pregnancy, immediately after a severe fall; recovery was rapid and uninterrupted. One year after the date of miscarriage her seventh child was born after

an apparently normal pregnancy, fetal life being felt at the beginning of the fifth month. Labor began at 3 A.M. and terminated naturally at noon of the same day, the presentation being that of face with left mtoanterior position. The child was a typical anencephalic monster with absence of both hemispheres, prominent eyes, and broad neck. Breath-sounds and heart-beats were present at the time of birth, but ceased a few minutes after the termination of labor. The weight and dimensions of the body were normal with the exception of the cranium. The placenta was found to weigh less than 1 pound, the lobules being interspersed with much connective tissue; the cord was centrally inserted.

The eighth delivery occurred 1 year and 10 months after; when 2 months pregnant a severe uterine hemorrhage occurred suddenly without apparent cause and without pain, the amount of blood lost being from 1 to 2 pints. One month later a second hemorrhage occurred in the same manner, being not quite so profuse as the first. From this time onward pregnancy progressed normally, fetal life having been first noticed the beginning of the fifth month. After a short labor of 7 hours a female child was born at term in the L. O. A. position, vertex presentation. The body was 53 cm. in length, and weighed 8 pounds. The position and size of the internal viscera were apparently normal. From the fourth dorsal vertebra to the sacrum the spinous processes of the vertebra were absent, the transverse processes being spread outward, thus greatly increasing the transverse diameter of the column. The meningeal coverings of the cord protruded in a sac, which contained a quantity of cerebrospinal fluid. The integument on either side of the spine was entirely wanting over the erector spinae muscles, their fibers being plainly visible.

An examination of the cranium showed it to be apparently normal, with the exception of entire absence of the occiput, the brain being felt distinctly beneath the skin as a soft pul-taceous mass; reflex action, produced by irritation of the exposed medulla (Herrgott's sign), could not be obtained.

Both feet presented marked talipes valgus and the left patella was entirely absent, allowing free articulation antero-posteriorly.

The child was apparently well nourished at birth, but nursed poorly and died at the end of the third week. Motion and sensation were present over the entire body until death.

The case seemed of interest because of the two anomalous births immediately following the other and the negative etiology.

CHOLECYSTOTOMY FOLLOWING EXPLORATORY INCISION FOR APPENDICULAR ABSCESS.

By G. C. KILGORE, M.D.,

of Allen, Pa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

Mrs. H., aged 27 years, mother of 5 healthy children, youngest 5 months old, previous health good, complained of cramps in the stomach at intervals of from 2 to 3 weeks, the attacks increasing in severity, but yielding to treatment consisting of free catharsis, local application of hot turpentine stupes, morphia, in sufficient doses to relieve the pain. June 26 the patient was taken suddenly with violent pain in the right epigastric and hypochondriac regions, acute nausea, and vomiting, temperature rapidly rising to 104°, marked tympanites and peritoneal tenderness being present.

The attending physician diagnosed the case as acute gastritis and enterocolitis and instituted the routine treatment for same. Four days later I was called in great haste to see the patient and found her suffering great pain, temperature 104°, pulse 140 and very weak; I was told that she had been unable to retain any food on her stomach since the onset of the attack, and that she had several chills during the day. Physical examination revealed a moderately distended abdomen with marked tumefaction. About 2 inches above, and 1 inch to the left of McBurney's point, I palpated what I supposed to be a pus sac of possible appendicular origin, and as the patient continued to have marked chills and was constantly growing weaker, I decided to operate without delay. I made hasty, but as thorough preparation as was possible

for an aseptic operation, and with the able assistance of Drs. Phillipy and Diven, of Carlisle, Pa. I made an incision above and to the left of McBurney's point, and found the intestine distended and inflamed, and the gallbladder greatly enlarged, and closely adherent to the gut. I carefully broke up the adhesions and made an incision about 1½ inches in length, through the neck of the gallbladder, and evacuated about a teacup full of pus, and a large quantity of serum, introducing my index finger I succeeded in extracting 11 gallstones of large size and several smaller ones, after which I irrigated with a normal salt-solution and closed the incision with catgut-sutures. I washed the abdominal cavity with a hot saline solution and hastily closed the incision with silkwormgut, not taking time to suture the peritoneum and fascia separately, but included all of the structures with the interrupted suture in order to hastily terminate the operation. After powerful stimulation the patient reacted and her strength was maintained by rectal alimentation for the next 6 days during which time she suffered only from hic-coughs. I would add that ice was constantly kept upon the wound, and that the wound healed by first intention. The patient made an uninterrupted recovery, and was able to sit up at the end of the fourth week, and she now enjoys the best of health.

It is not with the intention of adding anything to the knowledge of abdominal surgery that I report this case, but it demonstrates what may be accomplished by the general practitioner of the rural districts, even where the environments are bad, and no trained nurses, or hospital equipments are at hand.

During my brief experience as practising physician here in the country districts, I find the people greatly opposed to all surgical procedures however slight they may be, and this I believe to be occasioned by too great conservatism on the part of the country physicians, and I think it the duty of every regular practitioner to proceed fearlessly in those cases where operative measures are demanded, instead of catering to the popular demand of the people for medicinal treatment only.

The Treatment of Tuberculosis of the Larynx.—

R. Imhofer (*Prager medicinische Wochenschrift*, October 4, 1900) discusses the treatment of laryngeal tuberculosis with special reference to removal of the ulcerated area. In some of the milder cases the application of lactic acid is sufficient, but if there is considerable infiltration, curetment is essential. He advocates the use of Krause's double curet for most cases. In rarer cases Landgraf's curet or a simple curet may be employed. Krause's instrument consists of 2 cutting rings which bite off tissue like a forceps. Two instruments are made of this kind, one of which cuts in a sagittal, the other in a transverse direction. It is necessary to carefully anesthetize the area which is to be excised and a 20% to 25% solution of cocaine is recommended. Then by the use of the curet the diseased tissue is removed. It is important that the exact location of the instrument should be carefully determined by the laryngeal mirror before cutting. The hemorrhage in these cases he finds insignificant. Many patients who are suffering from severe pain, difficulty in respiration and in swallowing, and who have come under treatment in a condition considered hopeless, have been enabled to take nourishment without pain, and their respiration has become easier, and their general condition much improved. Imhofer believes that recovery is possible, even in severe cases. The duration of the process of healing depends upon the severity of the case. On an average it is about 6 months, and even then recurrences must be expected in many cases. Imhofer concludes that the surgical treatment of laryngeal tuberculosis is the most successful of which at present we have knowledge. A bad general condition and advanced local disease is no contraindication to the treatment. By this method of treatment the patient can suffer no harm, and there are possibilities of great improvement. Laryngeal phthisis, even in the advanced stages, he considers a curable disease. [M.B.T.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended December 29, 1900:

Monday, December 24—Neurological Society.
Wednesday, December 26—County Medical Society.
Thursday, December 27—Pathological Society.

A hospital for children will be erected at McKeesport by a request of Mrs. Pauline Auberle. Catholic charities also received \$250,000.

Entertainment at Jewish Hospital.—A musical entertainment was given recently to the inmates of the Philadelphia Home for Aged and Infirm Israelites at the Jewish Hospital.

The University of Pennsylvania recently received \$4,000 from a friend whose name has not been made public for the equipment of a physical laboratory in that institution. A fund of \$500 was also presented to be devoted to prizes.

Diseased Cattle Sent to New Jersey.—Suit has been brought against the Trenton Abattoir Company by the Board of Health of Trenton to collect penalties for bringing diseased cattle into the State. Recently 20 cows from Bucks county, Pa., were condemned as tuberculous and killed.

Impure Borax.—Steel manufacturers and wholesale druggists of Pittsburg have been cooperating for some weeks in the detection of the adulteration of borax, of which about 10 carloads are used in that city every week, largely in the making of steel. It has been found that 60% of the borax furnished to Pittsburg has been adulterated to the extent of from 40 to 65%. A crusade against this resulted in 20 arrests in Pittsburg last week.

Students of Medicine in Philadelphia.—The following is a list of the total number of students enrolled in the colleges of Philadelphia for the year 1900-1901: Jefferson Medical College, 752; University of Pennsylvania, Department of Medicine, 566; Department of Dentistry, 416; Medico-Chirurgical College, Department of Medicine, 416; Department of Dentistry, 120; Department of Pharmacy, 63; Woman's Medical College, 164; Philadelphia Dental College, 398; Pennsylvania Dental College, 298; Philadelphia College of Pharmacy, 442. This makes a total of 1898 students of medicine, 1224 of dentistry, and 505 of pharmacy.

Hospital for the Tuberculous.—With a view to raising \$10,000 for the purchase of a city home and a mountain site, the managers of the Free Hospital for Poor Consumptives of Philadelphia have just issued an appeal to the charitably disposed public for contributions, and an effort will be made to get the desired amount in a short time. The president of the institution, Dr. Lawrence T. Flick, calls attention to the fact that the idea of furnishing care and treatment for poor tuberculous individuals originated and was first put into execution in this city, and that the death-rate from this disease has been reduced one-third in this city since 1884. The organization is now appending \$1,000 a month for the board of tuberculous patients, this amount being raised by voluntary contributions.

The State Board of Health in its recent annual report states that the most important subject of legislation at the present time is the institution of safeguards for public water-supplies. The last legislature recognized 2 facts: First, that the State has a right to exercise control over public waters and to forbid their pollution; second, the State Board of Health is the proper body to enforce this authority. This law applies only to cities of the first class and efforts are being made to have it extended. Concerning school directors the report says: "The law authorizing school directors to assume certain functions of a board of health is still on trial. The fact that during the past year only 21 school boards have availed themselves of this opportunity to aid in the protection of the public health would seem to indicate that it does not commend itself to the great body of

school directors throughout the State. The entire number which have reported to the board as having assumed their new responsibilities is but 56 out of a possible 2700. The total number of cases of smallpox officially reported as having occurred in the State during the epidemic which began in December, 1898, is 1429 with 18 deaths. The report calls attention to the fact that the State Board favors the placing of pulmonary tuberculosis in the class of contagious and notifiable diseases.

Vital statistics of Philadelphia for the week ended December 15, 1900:

	CASES.	DEATHS.
Total mortality		369
Inflammation of appendix 1, brain 6, bronchi 7, kidneys 13, liver 1, lungs 53, peritoneum 9, pleura 2, stomach and bowels 14, tonsils 1		107
Lungs—tuberculosis of 47, edema of 3, hemorrhage of 3, abscess of 1		54
Marasmus 11, inanition 15, debility 2		23
Heart—diseases of 25, fatty degeneration of 2, Apoplexy 12, paralysis 6		27
Carcinoma of neck 2, bowels 1, brain 1, breast 2, esophagus 1, pancreas 1, stomach 5, uterus 2, abdominal tumor 1		18
Puerperal convulsions		16
Old age		14
Diphtheria	91	14
Casualties		11
Uremia 5, Bright's disease 2, diabetes 3,		10
Brain—diseases of 2, softening of 3		5
Epilepsy		4
Typhoid fever	87	4
Septicemia		4
Cirrhosis of liver		3
Bowels—tuberculosis of 1, obstruction of 2		3
Whooping-cough		3
Scarlet fever	76	2
Abscess of hand 1, liver 1, asthma 2, anemia 2, membranous croup 2, cyanosis 2, diarrhea 1, erysipelas 1, hernia 1, influenza 2, intussusception 1, measles 1, poisoning—corrosive sublimate 1, stricture of pylorus 1, suicide—hanging 1, shooting 1, syphilis 1, teething 2, tetanus 1, ulceration of stomach 1, unknown Coroner's cases 2		

NEW YORK.

To Prevent Smallpox.—As a result of the recent smallpox scare in Jersey City, 4,000 girls in Lorillard's tobacco factory have been vaccinated.

Typhoid fever still prevails in Sing Sing prison, 23 convicts being ill at present. The cause of the outbreak is thought to be a broken water pipe which runs through some old buildings that have outside closets.

Passaic River Polluted.—Much alarm is felt in Jersey City over the prevalence of typhoid fever. The water-supply comes from the Passaic River, which is said to be polluted. A committee of 18 prominent citizens has been appointed to take action in the matter.

No Arsenic in American Beer.—The United States Brewers' Academy of New York has analyzed various specimens of the glucose produced in this country and used in the manufacture of beer, the object being to ascertain whether the American product contains arsenic, as did, it is alleged, the glucose used in making the Manchester, England, beer, which poisoned more than a thousand persons recently. No trace of arsenic was found in any of the specimens.

Inspection of Barber Shops.—In consequence of complaints made of contracting barber's itch, the Board of Health of New York propose to enforce new sanitary regulations in all barber shops, and an inspection will be made to see that all implements used are sterilized in antiseptic solutions after each separate use. That a clean towel is provided for each person, that pure soap and running water is furnished, and that head rests and shaving cups are cleansed. The use of sponges and powder puffs will be prohibited.

The Society of the Lying-in Hospital in its recent report calls attention to the increase of 6% in the number of women treated by midwives, and also to the abuse and mal-

practice of this class, and the introduction of a bill at the last session of the Legislature to regulate the practice of midwifery in this State by others than legally authorized physicians. It also shows the accommodations at the disposal of the Department of Charities in the Borough of Manhattan for women in childbirth, and says that it finds it difficult to believe that the 68 beds for waiting women and 56 beds for childbirth cases are inadequate. Treating of the immigrant class, the report cites statistics to show that the average wages received by the husbands of women treated was \$29.84 per month, so that, rent paid, there remained about 70 cents per day on which to support and clothe each family. The data are given to show how impossible it is for these people to save anything for medical attendance.

The New York State Hospital for the Care of Indigent Crippled and Deformed Children, incorporated by the last legislature, is now open for the reception and treatment of patients. It is located at Tarrytown, N. Y., and has accommodations for about 30 patients. The board of managers appointed by Governor Roosevelt are the Right Rev. Henry C. Potter, Bishop of New York, president; George Blagden, Jr., secretary and treasurer; J. Hampden Robb, J. Adriance Bush, and Dr. Newton M. Schaffer. Patients from 3 to 15 years of age will be received, who have resided in the State of New York for a period not less than 1 year, and all applications will be acted upon in the order of their reception. No patient will be received except upon affidavit of guardians that he is unable to pay for private treatment. Application for admission should be made to Dr. Newton M. Schaffer, surgeon-in-chief, No. 28 East Thirty-eighth Street, N. Y., who will appoint a time and place for the examination of the patient. Patients living at remote points are referred to the following gentlemen, out-of-town members of the consulting staff: Dr. A. Vander Veer and Dr. S. B. Ward, of Albany, N. Y.; Dr. Louis A. Weigel, Rochester, N. Y.; Dr. Roswell Park and Dr. Charles G. Sockton, Buffalo, N. Y.; and Dr. Richard B. Coutant, Tarrytown, N. Y.

New York Neurological Society.—At a meeting December 4, 1900, Dr. WILLIAM M. LESZYNSKY presented a man, 21 years old, in whom the chief feature of interest was a trembling of the hands more marked on the left side which had existed as long as he could remember and was growing steadily worse. Dr. Leszynsky believed this man had recovered from a paralysis which he had had at one time and was now suffering from a **terminal condition of an infantile palsy**. Dr. M. ALLEN STARR said that 5 years ago he had been able to collect 145 cases of spinal tumor, in 22 of which operation had been undertaken. In the 2 cases forming the subject of the paper the symptom, pain, had been very prominent, and this together with the symptoms of pressure on the cord had allowed of the diagnosis being made. The tumors were both removed. In the discussion emphasis was given to the advisability of operating without delay as soon as a diagnosis had been established with reasonable clearness. **An analysis of the symptoms observed in cases of tuberculous meningitis at the Babies' Hospital.** Dr. C. A. HERTER read a paper with this title. There were 24 cases of tuberculous meningitis, and in 15 of these there were autopsies. In these 15 cases, 6 were at the age of 8 months; 7 were one year old or under. In 9 cases of tuberculous meningitis without autopsy, 6 were 5 months old. These figures showed that tuberculous meningitis was not so rare in the first year of life as had been supposed by some writers. Of the cases 19 had run their course in less than one month. An interesting feature was that at times the knee-jerks would be alternately exaggerated and absent.

New York Academy of Medicine.—At a meeting of the Section on Orthopedic Surgery, November 16, 1900, Dr. T. H. MYERS presented a baby, 1 month old, under treatment for **fracture of the femur**, which occurred at birth, just below the trochanter minor, with the very unusual displacement of the lower end of the upper fragment backwards. A plaster-of-paris jacket was applied in which was incorporated a steel bar, $\frac{3}{4}$ by $\frac{1}{4}$ inch, extending from the angle of the scapula to the toes, and bent at a right angle at the buttocks and the heel. Traction was made and eversion overcome by adhesive plaster applied to the limb and fastened to the steel foot-piece. The plaster of paris enclosing

the pelvis provided secure countertraction. A light plaster-of-paris bandage secured the limb to the splint and held back the upper end of the lower fragment. A fenestrum permitted the dressing of the cord. The child fell asleep at once on this application. No displacement. Shortening $\frac{1}{2}$ inch. Dr. JUDSON presented a girl, 7 years of age, with symptoms of **disease of the left hip** of 12 weeks' duration. On presentation the child walked when the splint was off with no defect in her gait. An ischiatic crutch had been applied to be worn in the daytime with a high sole on the well foot, directly to relieve the limb from the labor of locomotion and the affected bone from bearing the weight of the body, and ultimately to permit the resolution of the inflammation by natural processes. Dr. Judson also presented a boy of 7 years of age slowly convalescing under mechanical treatment for **white swelling** of the left knee. A year ago the patient's general condition was most unfavorable, and locally there were sinuses surrounding the knee, great swelling and the usual evidences of a disintegrating joint. In spite of the most unfortunate and discouraging environment, improvement had been marked generally and locally. The treatment was by a fixative brace worn day and night, and an ischiatic crutch worn only in the daytime. Prognosis was in favor of a useful limb, of good length, with no flexion and no deformity except a slight and unimportant degree of subluxation. Dr. TAYLOR reported the case of a girl, 6 years of age, an instance of **typical funnel chest** of moderate degree. There were no evidences of rickets and the child's health was good. She was the fifth child in a family of 7. Her mother had the same deformity, but knew of no other cases in the family. Dr. GIBNEY exhibited a specimen from a patient, 5 years old, affected with **Pott's disease with deformity**, who died unexpectedly in the night with **abscesses arising from carious vertebrae**. He had seen no less than 6 children die in a similar manner. Autopsies had not made clear the cause of death.

New York's Vital Statistics.—According to the report of the Health Department for 1899, made public only recently, the health of the city in that year was excellent; 65,343 deaths were reported, giving a death-rate of 18.41 per thousand. The city rate was lower than that of any of the large cities of Europe. In London the rate was 19.80, in Paris 20.20, Berlin 18.70, Vienna 20.60. The death-rates for past years are as follows: 1880, 26.41; 1885, 25.55; 1890, 24.87; 1895, 23.11; 1896, 21.52; 1897, 19.53; 1898, 19.23. There were reported 33,486 cases of contagious diseases—nearly 4,000 less than in 1898. Only one borough, Richmond, showed an increase, due to scarlet and typhoid fever; in the Bronx these cases diminished by 50%. Infant mortality also showed a marked decrease as compared with 1893. The sanitary bureau made 1,632,672 inspections and reinspections in the course of the year, and preferred 79,019 complaints; 40,282 complaints were received from citizens, also. Inspection of foodstuffs resulted in the seizure and condemnation of 10-274,930 pounds of milk, fruit and fowls, meat and fish, and the imposition of fines aggregating \$5,770. Bananas and melons made up the largest item of seizures—3,149,697 pounds of the former and 1,817,765 pounds of the latter. As a result of school inspection, 9,367 out of 12,8787 pupils examined were excluded from school. About $\frac{1}{2}$ of these were in the primary grades. Deaths by accident numbered 2,620, 1,563 of which were in Manhattan. Falls caused 643 deaths; burns and scalds, 355; drowning, 252; 269 were killed on railroads; sunstroke killed 141, and poison 221. The births aggregated 77,632, over 12,500 in excess of the deaths. January, March, and August lead in the number of births; May had the fewest, 5,792. In that year 8 women 100 years of age and over died; the oldest was 104 years 7 months 2 days.

NEW ENGLAND.

Waltham Hospital, Mass.—The hospital authorities are considering plans of enlargement, and 15,000 square feet of land from Mt. Feake Cemetery, which adjoins the hospital land, have been given to the trustees by vote of the Waltham Board of Aldermen.

Home for Feeble-Minded Children.—The Milford Woman's Club of New Hampshire proposes to establish a home for the feeble-minded in that State. The project is to be submitted to all the women's clubs in the State, and a sub-

scription list, headed by the Milford club, with a contribution of \$50 and a pledge for an annual gift of \$25, to support the home, will be presented. It is believed that there will be a general response.

Helen Keller, the deaf, blind, and previously dumb student at Radcliff College, recently made a brief address to the freshman class, of which she is a vice-president. Her words were few, spoken in a low, musical, unmodulated voice, which was not lacking in strength, and could be understood quite readily by those accustomed to her. She is now 19 years of age, and is making a steady improvement in her new achievement.

CHICAGO AND WESTERN STATES.

Bequest to Hospital.—H. M. Hanna, brother of Senator Hanna, has turned over to the trustees of the Lakeside Hospital, of Cleveland, 1,000 shares of the Northern Pacific Railroad, valued at \$81,500.

Verdict.—The suit of Dr. James W. Crewdson, of Louisiana, Mo., for medical services to the late Fielden Estes, amounting to \$6900, was concluded November 24, when the jury returned a verdict of \$2375 for the plaintiff.

State Sanatoriums.—At a recent meeting of the Board of Health of Alameda, Cal., a resolution urging legislative action to provide for the establishment and maintenance of State sanatoriums for the care of the tuberculous was unanimously adopted.

Practising Without Certificates.—Warrants have been issued for the arrest of 3 women and 1 man, of Los Angeles, California, charged with practising medicine without having obtained certificates from the State Board of Medical Examiners.

The Bethesda Hospital for Incurables at St. Louis was opened December 1. The building is the gift of Mr. R. M. Scruggs, of St. Louis, and cost over \$70,000. It has facilities for the accommodation of 80 patients, an excellently fitted operating room, and an isolated ward for the treatment of contagious diseases.

Diploma Dealer Sentenced.—James Armstrong, president of the Metropolitan and Independent Medical College, and the Illinois Health University, institutions in Chicago devoted exclusively to the sale of bogus diplomas, has been adjudged guilty of using the United States mails to defraud and sentenced to serve one year in jail and pay a fine of \$500.

Indians Disobey Sanitary Laws.—A special from White Rock, Utah, says that at the request of Agent Myton, Troop K from Fort Duchesne has been ordered out to prevent trouble at the Wintah agency. Over 30 children in the school are down with measles and other diseases, and their parents have been much dissatisfied because the children were not allowed to go home.

The Chicago Pathological Society held a meeting December 10, 1900. Dr. Zeit read a paper on **Uretero-intestinal anastomosis**, illustrated by gross and microscopic specimens, and by photographs and drawings. The paper discussed an experimental study of the pathology and bacteriology of ureteral implantation into the rectum as practised on 120 dogs and implantation of the trigonum into the rectum on 21 dogs. The operations were made with a view of devising an operation for cases of malignant disease of the bladder. The conclusions reached are that no matter what is the operation employed with a view of preventing ascending renal infection, the pathology of ureteral implantation into the rectum is the pathology of pyelonephritis and its sequels. All the variations of this form of suppurative nephritis were observed in the operated dogs, from the earliest beginning of ascending infection a few days after the operation up to the healed process with induration and cicatrization and resulting granular contracted kidneys. Operative results on 21 dogs with implantation of trigonum into rectum were more favorable. A number of experiments on white mice and guinea-pigs were described, undertaken with a view of producing an artificial immunity to in-

fection with *Bacillus coli*, but the serum of immunized animals only clumped bacilli used for immunization. Intraperitoneal injections of other virulent cultures of *Bacillus coli* proved pathogenic to other animals immunized by virulent colon bacilli obtained from other sources. The experiments are being continued. An artificially produced immunity to the group of colon bacilli appears to be the only hope of making ureterointestinal anastomosis a feasible operation.

SOUTHERN STATES.

A Physician as Secretary of State.—The newly elected governor of Maryland has recently appointed as secretary of state Dr. C. R. Layton, a practising physician of Georgetown.

The New Orleans Board of Health is seriously handicapped by the Council which curtails the expense appropriations of the board. The last requisition of \$25,000 was cut down to \$5,000.

The Association for Improving the Condition of the Poor, of Baltimore, has recently received a bequest of \$60,000, left to the association by the will of the late Mr. Jacob Craft Whittington.

Scarlet fever has spread over the middle and upper Carolinas. The Board of Health has closed the churches in Seneca, prohibiting gatherings of all kinds. Last week Clement College was closed on account of the prevalence of the disease.

The Orleans Parish Medical Society held a meeting on December 8, 1900. The following officers were elected: President, E. D. Martin; vice presidents, H. B. Ceesner, L. C. LeBeuf, and George Stumpf; secretary, W. H. Perkins; treasurer, M. H. McGuire; librarian and corresponding secretary, S. P. Delaup.

The New Orleans Charity Hospital will soon have 100 nurses added to the present corps and thus provide trained nurses for the male medical and surgical wards. A special building for the accommodation of the nurses will also be erected at the cost of \$25,000. Plans for this building will be submitted at the next meeting of the board of administrators.

Cocain Drunkenness.—An order has been issued to the police of New Orleans by Chief of Police Caster to arrest all persons dealing illegally in cocain or suffering from cocain drunkenness. The order said: "The constant use of cocain has assumed large and serious proportions and is daily increasing to such an extent as to be a menace to public health. You are directed to notify the force under your command to use extreme diligence in enforcing the city ordinance against the use of cocain and to make arrests. This menace is general throughout the city. This order must be strictly adhered to, and you will make written reports to this office of each offender arrested and from whom the drug was purchased, whether from a druggist or pedler."

Homeopaths Seek Recognition in Municipal Hospital.—A memorial has been presented to the Commissioners of the District of Columbia by the Homeopathic Medical Society which recommends that a plan be devised whereby a fixed proportion of patients be assigned to a homeopathic department in the proposed Municipal Hospital. This, it is suggested, shall be done preferably by establishing separate buildings, or wings, for the respective systems. It is stated that this demand for representation is made after conference with the respective medical societies of the District, and it is suggested that the proposition should be definitely determined before an application for appropriation is submitted to Congress.

CANADA.

Toronto Medical Schools.—Steps are being taken to combine the Toronto Medical College and the Trinity Medical College of the same city. Representatives of the 2 faculties held a meeting, and a committee composed of 3 members of each faculty has been appointed to draft a definite basis of amalgamation.

A Hospital for Women.—It is reported that a committee of women has been appointed in Toronto, Canada, to formulate a scheme for the maintenance, in connection with the Women's Medical College, of a Women's Hospital for Ontario, in which all the operations shall be performed by women surgeons, and the resident physicians shall also be women.

MISCELLANY.

Dr. Velde, of the German Legation at Pekin, has been tendered, through Andrew D. White, the United States Ambassador, America's sincere gratitude for the services rendered by him to American soldiers and sailors during the siege of Pekin.

Reoccupation of Tortugas.—The Navy Department has been advised that the Marine-Hospital Service is about to abandon its quarantine station at Dry Tortugas. This will permit the Navy Department again to occupy the coaling and repair station upon which the yellow fever season interrupted the work of the constructors.

Chocolate for Soldiers.—The merits of chocolate as food for troops in the field appear to be greatly appreciated. In the recent autumn maneuvers of the Austrian Army in Galicia, a chocolate ration was found to be equal to about 5 times its weight of the best beef. From Russia also come equally favorable reports. In this country it forms a chief constituent of a new emergency ration with which trials have been lately carried out.

Surgeons in the Navy.—The Surgeon-General of the Navy, in discussing the difficulties in securing officers for his corps, is reported to have said that he did not understand why men did not wish to be examined, that many who have made inquiries in regard to the examinations have afterwards gone into the Army. Notices have been published in regard to the betterment of the condition of the assistant surgeons and to the number of vacancies. The Surgeon-General says that fully one-third of those who apply for admission to the medical corps are found physically disqualified.

Mosquito Inoculation.—A cablegram to Surgeon-General Sternberg announces that the recent experiments with mosquito inoculation have been completely successful in 80% of the cases under treatment. These experiments are being conducted by Dr. Reed and other surgeons of the army near Havana. They are based upon conclusions reached by Major Reed and other medical officers recently appointed to conduct scientific investigations with reference to the acute infectious diseases prevalent in Cuba. So far the treatment has been limited to Spanish immigrants desirous of immunity to yellow fever who have voluntarily presented themselves for inoculation with an understanding of the nature of the experiment.

Resignation of Dr. Anita Newcomb McGee.—The only woman with the rank of lieutenant in the army has resigned. Dr. Anita Newcomb McGee, daughter of Simon Newcomb, the astronomer, was appointed acting assistant surgeon in the United States army in August, 1898, to aid in the selection and equipment of a corps of army nurses for field and hospital work. The appointment carried with it the rank of first lieutenant and the right to wear the shoulder-straps and uniform of an officer of that grade, a right of which she did not avail herself. The work for which she was appointed having now been fairly organized, Dr. McGee has resigned, and no successor will be named. In accepting her resignation, Surgeon General Sternberg has complimented Dr. McGee highly upon the services she has rendered.—[Springfield Republican]

Obituary.—JAMES FLUERY STEWART, of Cold Spring Harbor, L. I., December 11, aged 24.—O. R. EARLY, of Columbus, Mississippi, December 11.—PETER F. CURLEY, of Newport, December 13, aged 39.—JOHN C. ACHESON, of New York, December 12, aged 68.—W. H. JONES, Medical Inspector U. S. Navy, retired, of Bethlehem, Pa., December 13, 1900.—S. HOFFNER, of Hamilton, Ontario, December 14, aged 49.—JOHN IGNATIUS GROSS, of Baltimore, December 14, aged 69.—DAVID AVISON, of Colorado Springs, December 6.

—GREGORIO DE QUESADA, in New York, December 5.—J. A. LORD, of Edgerton, Wisconsin, December 3, aged 42.—WALTER C. PEASE, of Cumberland, Wisconsin, December 6.—W. C. MOORE, of Clarkstone, Georgia, December 3.—ELLIOTT BARTON PALMER, of Cincinnati, December, aged 30.—W. S. BUNN, of Lawrence, Kansas, December 13, aged 45.—D. R. HOKE, of Water Valley, Miss., December 13, aged 75.—N. B. JONES, of Belle, Missouri, December 13, aged 50.—HENRY B. FELLOWS, of Chicago, December 15, aged 63.

Health-Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, for the week ended December 14, 1900:

SMALLPOX—UNITED STATES.				CASES.	DEATHS.
CALIFORNIA:	Oakland	Nov. 24-Dec. 1	4		
GEORGIA:	Houston	Dec. 1-7	24	1

PHILIPPINE ISLANDS:	Manila	Oct. 13-20	3	2
---------------------	----------------	--------------------	---	---

Smallpox still prevails in many parts of the United States. From New York 54 cases have been taken to North Brother Island. Of these 8 have been discharged as cured and 3 have died. Dr. Blauvelt, of the Bureau of Contagious Diseases, is reported to have said that at least a million people had been vaccinated since the outbreak began. In Schenectady, N. Y., 3 cases are being treated in a pest house. The disease exists in an Indian camp near Spokane, and 1 case is reported at Walla Walla, Wash. In Washington, D. C., 6 new cases are reported. There are 8 cases in the hospital. The smallpox situation in Eastern Utah is reported alarming. The greater number of the cases are among the foreign-born miners in the coal camps. There are about 100 cases at Scofield, while Winter Quarters, Clear Creek and Sunnyside Camp, in the east end of Carbon County, report

numerous cases. In St. George's Hospital, Kansas City, Mo., there are 40 cases. Only 1 death has occurred from the disease. The Council of Yukon, Alaska, has ordered that every person in that section of the Yukon territory be vaccinated at once. This district contains about 12,000 people. The Council ordered 12 500 vaccine points, of which the first shipment was expected by mail about November 15. Six Dawson physicians were employed at \$30 a day each to go out on the creeks and vaccinate all who have not been vaccinated within 7 years. No deaths have yet occurred from smallpox.

The Navy Ration.—Surgeon James D. Gatewood, at present assistant chief in the bureau of medicine and surgery, according to the *Army and Navy Register*, has made these statements in official form to the department: "There are many reasons why a recruit should be allowed his outfit, for the lack of money affects his welfare in many ways. Not the least of these is the relation to the question of food. No men long in the navy depend solely upon the regulation ration. Whatever may be the scientific relations of the navy ration it does not satisfy, and the amount that is utilized is not sufficient by itself to prevent the craving for additional food. Undoubtedly not a little of the dissatisfaction can be traced to the fact that the cooks are unskilled, as it has not yet been regarded as essential in the Navy to train men for that important duty. But much of the discontent has its source in the ration itself. It does not seem to be generally recognized in the service that the ration is much overvalued. It seems fair to state that while it issued at a value of 30 cents its actual cost is now only about 18. As a result, when a ration is commuted the money not only secures a necessary additional variety and a better relation of nutritive substances, but adds largely to the calories, thus producing a distinct gain from a scientific point of view. Yet even with that increase, messes composed of men long in the service find it necessary to add to the fund secured by the commutation of 25% of the rations. The amount contributed by each member varies in different messes from \$2 to \$5 a month.

Changes in the Medical Corps of the U. S. Army, for the week ended December 15, 1900:

BAHR, WILLIAM, hospital steward (appointed December 3), now on temporary duty at Rock Island Arsenal, Ill., will be sent to his proper station, Fort Leavenworth, upon the return to duty of Hospital Steward Isaac C. Clarke.

DEMEY, CHARLES F., acting assistant surgeon, having relinquished unexpired portion of leave is assigned to duty with troops on the transport "Meade," to sail for the Philippine Islands about December 1.

PINTO, ALVA S., acting assistant surgeon, is relieved from temporary duty at the Army General Hospital, Presidio, and assigned to temporary duty with troops on the Army transport "Meade" to sail for the Philippine Islands about December 1.

TREW, NIEL C., acting assistant surgeon, is granted leave for 1 month from December 1.

MCCULLOCH, JR., Captain CHAMPE C., assistant surgeon, will proceed to Manila, P. I., upon the Army transport "Meade," to sail about December 1. Upon arrival at Manila, Captain McCulloch will report to the commanding general, division of the Philippines, for assignment to duty.

FRASER, SIMON J., acting assistant surgeon, now in this city, is assigned to temporary duty with troops on the Army transport "Meade," to sail for the Philippine Islands about December 1. Upon arrival at Manila, Acting Assistant Surgeon Fraser will report to the commanding general, division of the Philippines, for assignment to duty.

WILSON, RICHARD, acting assistant surgeon, is granted leave for 1 month.

MCCULLUM, FRANCIS M., acting assistant surgeon, now at Kansas City, Mo., will upon the expiration of his present leave, of which he availed himself at San Francisco, Cal., proceed to Jefferson Barracks for temporary duty.

WILSON, COMPTON, acting assistant surgeon, is granted leave for 1 month from December 7.

STOCKARD, JAMES K., acting assistant surgeon, is granted extension of leave to include January 19.

GOULDING, T. F., acting assistant surgeon, leave is extended 1 month.

WILLIAMS, ABRAHAM D., acting assistant surgeon, now in New York City, will proceed to Jacksonville, Fla., and report by letter to the Surgeon-General of the Army for annulment of contract.

KELLER, WILLIAM L., acting assistant surgeon, is relieved from temporary duty at Fort Logan and will proceed to San Francisco, Cal., for assignment to duty with troops en route to the Philippine Islands, where upon arrival he will report to the commanding general, division of the Philippines, for assignment to duty.

WILLIAMS, ABRAHAM D., acting assistant surgeon, having reported to the Surgeon General of the Army en route to Jacksonville, Fla., in compliance with orders of December 7 will proceed to San Francisco, Cal., for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines for assignment to duty.

BYRNE, JOHN G., acting assistant surgeon, now at San Francisco, Cal., will proceed to Fort Wright for duty.

GOULDING, TIMOTHY F., acting assistant surgeon, is granted leave for 1 month with permission to go beyond the limits of the division of Cuba.

MENDOZA, F. F., acting assistant surgeon, is granted leave for 1 month.

WALES, Captain PHILIP G., assistant surgeon, having reported his arrival at San Francisco, Cal., will proceed to Fort Duchesne.

BACON, JOHN E., acting assistant surgeon, is relieved from duty at Fort Duchesne, to take effect upon the arrival at that post of Assistant Surgeon Captain Philip G. Wales, and will proceed to San Francisco, Cal., for assignment to duty with troops destined for the Philippine Islands, and upon arrival at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

The following changes in the stations of officers are made: First-Lieutenant SANFORD H. WADHAMS, assistant surgeon, is relieved from further duty in the department of Puerto Rico, and upon the expiration of leave granted him October 13 will report at Columbus Barracks, Ohio, for duty. Upon the arrival at Columbus Barracks, of First-Lieutenant SANFORD H. WADHAMS, assistant surgeon, Major TIMOTHY E. WILCOX, surgeon, is relieved from duty at that post, and will report to the commanding general, department of the Lakes, Chicago, Ill., for duty as chief surgeon of that department.

Changes in the Medical Corps of the U. S. Navy, for the week ended December 15, 1900.

PEARSON, J. F., pharmacist, ordered to the Naval Academy.

PRYOR, J. C., assistant surgeon, detached from the "Albatross" on reporting of relief and ordered home to wait orders.

BUTLER, C. S., assistant surgeon, detached from the "Independence" and ordered to the "Albatross."

DENNIS, J. B., assistant surgeon, detached from the "Wheeling," on reporting of relief, and ordered home and to wait orders.

FISKE, C. N., assistant surgeon, detached from the naval hospital, Mare Island, Cal., and ordered to the "Wheeling."

WHEELER, W. M., passed assistant surgeon, detached from the "Kearsage" and ordered to the "Alabama."

RICHARDS, T. W., passed assistant surgeon, detached from the "Alabama," and ordered to the Bureau of Medicine and Surgery, Navy Department.

PLEADWELL, F. L., passed assistant surgeon, detached from the Bureau of Medicine and Surgery, and ordered to the "Kearsage."

Changes in the U. S. Marine-Hospital Service, for the week ended December 13, 1900:

AUSTIN, H. W., surgeon, detailed as medical officer in command of the national quarantine service on the Delaware Bay and river. December 5.

MEAD, F. W., surgeon, granted leave of absence for 1 day. December 7.

CRAIG, R. C., acting assistant surgeon, granted leave of absence for 7 days from December 19.

WALERTUS, M., senior hospital steward, granted leave of absence for 7 days from December 4.

CRAIG, JAMES, hospital steward, died at Key West, Fla., December 2.

Radical Cure of Hernia.—Shepherd (*Montreal Medical Journal*, October, 1900) says certain principles underlie all operations for hernia—first, the excision or obliteration of the sac; second, closure of the canal; and, third, union by first intention. He has employed all the recognized methods and prefers Bassini's. Some form of absorbable suture is much the best. The author asserts that no suture will hold longer than 3 or 4 weeks tissues which are on the stretch. They will simply cut out and lie loose in the tissue. So no advantage is gained in using suture material which lasts longer than this. He prefers chromicized catgut. It is better to dissect out the sac with a knife than to tear it out with the fingers. Never cut the internal oblique nor transversalis in transplanting the cord, merely pull the edges aside. The incision should be made well above Poupart's ligament so that after suturing the conjoined tendon to Poupart's ligament there is sufficient of the external oblique muscle left to suture to its upper portion. The patient should be kept in bed for 3 weeks. The author has adopted rubber gloves, and believes his improved results warrant their continued use. [A.B.C.]

Foreign News and Notes.

GREAT BRITAIN.

Owen's College, Manchester.—The late Dr. D. J. Leech, professor of materia medica and therapeutics in this institution, leaves £10,000 to endow a chair of materia medica and therapeutics.

The Surgical Aid Society, which furnishes gratuitously surgical instruments of all descriptions to the afflicted poor, has received a bequest of £30,614 by the will of Edward Mackeson, of London.

Journal of Hygiene.—A quarterly publication edited by Dr. G. H. F. Nuttall, will issue its first number, January 1, 1901, from the *Cambridge University Press*. Its scope will be similar to that of the *Archiv für Hygiene* and *Zeitschrift für Hygiene* and it will, it is hoped, be the chief medium for original workers among English-speaking people.

Palmistry.—A young woman was recently brought before the Torquay bench of magistrates charged with professing to tell fortunes by palmistry with intent to deceive; she was fined 10s. and costs. The letters F. B. I. M. S. were printed outside the door of her rooms and were explained by her solicitor to mean: "Fellow of the British Institute of Mental Science."

CONTINENTAL EUROPE.

Prince Gustavus Adolphus, the eldest son of the Crown Prince of Sweden and Norway, is reported ill with diphtheria.

Sun-baths are frequently prescribed by Berlin physicians for nervous complaints. An establishment has recently been opened in Strelau, a suburb of Berlin, for the giving of these baths.

The first tuberculosis sanatorium for the Portugal poor has been opened in the old fort of Ontao, on the sea-coast, near Setobal, with capacity for 100 patients. It is under the patronage of the Queen of Portugal.

To honor the memory of Pasteur the Stockholm Medical Society will give a gold medal every 10 years. Max von Pettenkofer, of Munich, received the first medal. The receiver must be a scientist whose works have done most to promote bacteriology or hygiene.

The notification of contagious diseases has been made compulsory on the attending physicians by the Spanish Government, a royal decree to that effect being issued October 10, 1900. The diseases are not specified in the decree, and no provision seems to be made for its proper execution.

Paris is said to be the cleanest city in the world. Every morning 2,000 male and 600 female scavengers, divided into 149 brigades, turn out to perform the toilet of the capital. The men work from 4 in the morning till 4 in the evening, less 2 hours off for meals, or 10 hours a day. The women are engaged in the morning only.

German Medical Examinations.—A bill regulating the entrance to the medical profession has been sent by the Imperial Government to the Bundesrath. It prolongs the period of study to 5 years, enlarges the subjects upon which the examinations are based and provides for 1 year of practical work before a license can be granted to practise.

Antimalarial Vaccine.—The *British Medical Journal*, in stating the claims of Dr. Kuhn, medical officer to the German troops of the South West African Protectorate, who is said to have discovered a method of curing malaria and of affording complete immunity to its attacks by inoculating patients in the very height of the malarial paroxysms with an organic liquid obtained from horses suffering from an epizootic prevalent there—probably that known as horse

sickness—laments the vagueness of the information, particularly as to the nature of the organic fluid which has such effect.

Horseflesh as a Food.—It appears from a series of experiments reported in the *Revue Général des Sciences* (Paris), that the popular prejudice against the use of horseflesh as food has some physiologic foundation, since the experimenter, M. Pflüger, found that its exclusive use as a diet is injurious. As he has also discovered a simple antidote to its harmful effects, however, the heroes of future sieges need not hesitate to employ it as a food. If one wish to use horseflesh as a food, it is a good plan, to avoid intestinal troubles, to add the kidney fat of beef or mutton, in the proportion of about an ounce of fat to 2 pounds of meat. It is also a good plan to boil the meat in water and to throw away the bouillon.

Against Tuberculosis in France.—From a summary issued by Dr. Léon Petit it appears that the recommendations of the special commission appointed by the French Minister of Public Instruction are: That the Public Health Bill now before the Senate be passed, with the addition of certain clauses relative to the sanitation of dwellings; that tuberculous patients in hospitals be isolated, precautions being taken to secure the antisepsis of wards and the protection of the staff; that in the army and navy, in prisons, etc., special measures of prevention be adopted; that tuberculosis be included among contagious diseases; that attention be paid to the prophylaxis of tuberculosis in railways. The necessity of an active antituberculosis propaganda is insisted on, and it is urged that preventive measures be taken in all places and collections of persons under the direct control of the State. The commission also recommends a stricter regulation of the meat and milk supply, and the adoption of measures for the repression of alcoholism as an accessory cause of tuberculosis. Dealing with curative measures the commission lays down the conditions required in a sanatorium, and urges that facilities should be provided for the treatment of poor children in seaside hospitals. It recommends the establishment of antituberculosis dispensaries in towns, and a more liberal application to tuberculous persons of the law of July 15, 1893, which should be made easily applicable to small communes. It now remains for the French Government to see that the recommendations of the commission are carried out.—[*British Medical Journal*.]

MISCELLANY.

Typhoid in South Africa.—It is reported that a question put to the Government in the House of Commons recently elicited the statement that there had been 15,625 cases of typhoid fever among the British troops in South Africa and that of this number 3,642 proved fatal.

Obituary.—E. T. GRIFFITHS, of Birmingham, November, aged 77.—JOHN IRON BEVAN, of Swansea, November 30, aged 53.—JAMES CARROLL, of Dublin, November 27.—GEORGE VERNON CURRIE, of London, December 3, aged 72.—CHARLES BARRY HART, of Torquay, November 25, aged 67.—PETER CORMACK SUTHERLAND, of Colony of Natal, November 30, aged 79.

Rattlesnake Polson as a Cure for Leprosy.—Dr. Adolpho Mercondes de Moura, of St. Paulo, Brazil, contributes a paper on the application of rattlesnake poison to the cure of leprosy to *The German Medical Weekly Journal*. This poison has been used for a long period by the natives for the treatment of skin diseases and even leprosy. Many wonderful cures of lepers through rattlesnake bites having been reported to him, Dr. de Moura set himself to make investigations. He experimented with the poison on 15 lepers, and he has come to the conclusion that the lepra tuberculosa if not complicated with another disease, is curable by its means. Professor Lewin, of Berlin, discusses the subject in the same number of *The Weekly Journal*. While he contends that the rattlesnake poison is not a true antidote, nevertheless he admits that it may have a temporary effect on the disease, and considers the matter worthy of investigation.

1.—Sawyer divides insomnia into secondary insomnia and intrinsic insomnia. Secondary insomnia is due to pain, elevation of temperature, frequent coughing or dyspnea. For the therapeutic control of this kind of insomnia we may employ remedies that directly cause sleep or measures that combat the cause of the insomnia. Intrinsic insomnia is a simple inability to sleep. It is convenient to arrange the different clinical varieties of this form of insomnia into groups, in which the cause of the affection is the principle of division. These groups are (1) the psychic, (2) the toxic, (3) the senile. The majority of the subjects of the psychic variety of insomnia are men of the nervous temperament; unnatural excitation of the cerebral cells is probably the initial fault. In the toxic variety the cause of the sleeplessness acts primarily upon the bloodvessels of the brain, giving rise to some degree of arterial hyperemia. The poisons concerned in the production of the symptom are the milder noxious agents such as tobacco, alcohol, tea, coffee, and the autogenetic poisons that accumulate in the bodies of the gouty persons or of those whose kidneys are inadequate. A smoker who suffers from insomnia may find the cure of his sleeplessness in the restriction of his smoking and the same may be said of habitual users of alcohol, tea, and coffee. [J.M.S.]

3.—Annandale finds the 3 most common places for congenitally misplaced and undescended testicles are: (1) On one side of the perineum (most common); (2) in the region of the eaphenous opening; (3) in front of the pubes at the root of the penis. In operating on these cases he proceeds as follows: An incision is made so as to expose the spermatic cord and its junction with the testicle; then the cord and testicle are drawn out and all attachments fixing the latter in its abnormal position are carefully divided. The corresponding side of the scrotum is opened with the finger and the testicle placed in it, 2 catgut or silk stitches are passed through those portions of the gubernaculum still attached to the testicle where they had been divided and these same stitches are also passed through the base of the scrotum to fix the testicle in its proper position, after this the opening through which the testicle had passed into the perineum is carefully stitched up by means of subcutaneous catgut sutures, and lately he has been carrying the stitch that passes through the gubernaculum and scrotum through the thigh also; this makes a steady traction on the testicle and

holds it in position. He also reports 2 cases of congenital absence of the testicle, although the vas deferens was in its proper position. [W.S.N.]

4.—As a result of experimental inquiry Pavy has been led to consider that by the following 3 processes the carbohydrate of the food is disposed of in the villi of the small intestine and in the liver, and thus prevented from reaching the general circulation as sugar: 1. By transformation into fat. 2. By synthesis into proteid. 3. By transmutation into glycogen. In the **pathology of diabetes**, if for any reason one of these processes fails to dispose of its proportion of carbohydrate, we get the alimentary form of glycosuria. In the more grave form of diabetes the sugar eliminated in the urine is derived partly from the breaking down of the tissues of the body and partly from the food. [J.M.S.]

5.—Brunton noticed that in patients suffering from **alcoholic neuritis**, before the loss of the knee-jerk and the extreme hyperesthesia of the skin appear, the **face** becomes mask-like and expressionless, the lips appear to move apart from the cheeks, and, what is sometimes still more extraordinary, the lips themselves may seem very mobile. The eyebrows and the eyes may move in accordance with the lips, but a fixed and expressionless band stretches across the nose and cheeks between the eyes and lips, the skin upon the cheeks remaining motionless and unwrinkled, while the lips, eyebrows, and forehead may be moving freely. The author also noticed that the reflex of the **pupil** to light at the same period of the disease is rapid and extensive, whereas the contraction of the pupil on accommodation to a near object is slight and sluggish or entirely wanting. Indeed in one or two cases a dilation instead of a contraction on accommodation was recorded. [J.M.S.]

6.—Thompson and Turner conclude: 1. That the primary element in the causation of **congenital stridor** is a disturbance of the coordination of the respiratory movements, probably due to some developmental backwardness of the cortical structures that control them. 2. That the change of form of respiration found is merely an exaggeration of the normal infantile type, and is mainly, if not entirely, the result of a constantly recurring sucking-in of the upper aperture of the soft larynx, which is induced by the ill-coordinated and spasmodic nature of the breathing. That it is, in fact, an acquired deformity strictly analogous to pigeon-breast. 3. That there is no proof that any congenital malformation of the upper laryngeal aperture exists in these cases. 4. That the supposition of a congenital deformity is not essential to account for the symptoms. 5. That the sounds are not produced in the pharynx, and that they are not produced in the trachea by compression exerted by a large thymus or enlarged lymphatic glands. This latter conclusion is drawn on two grounds: First, because in none of the fatal cases of congenital stridor recorded have enlargement of the thymus or lymphatic glands been noted; and, second, because in 2 cases that the authors have examined, in which compression of the trachea by enlarged bronchial glands was found after death, the symptoms were of a very different type. In these cases the stridor was mainly expiratory; the larynx did not move up and down with respiration as it does in cases of intralaryngeal obstruction, and there was much greater respiratory distress. The stridor is probably produced partly in the larynx proper, and partly at the abnormally approximated aryepiglottic folds. 6. That the neurosis causing the symptoms has not seemed to depend on the presence of adenoid growths or other obvious causes of reflex irritation. [J.M.S.]

7.—Pope and Clark report the case of a man, aged 38 years, who was suffering from **akromegaly** as indicated by the occurrence of a gradually progressive localized symmetrical hyperplasia of both bones and soft parts of the forearms, wrists, hands, and feet; bitemporal hemianopsia, lassitude, rheumatic pains of long duration, absence of vomiting, optic neuritis, and giddiness. The eldest child of the patient, a girl, aged 20 years, was a sufferer from a condition diagnosed to be infantile myxedema. [J.M.S.]

9.—Maguire sets forth some of the features that influence the **prognosis of pulmonary tuberculosis**. Lack of resonance and deficiency of breath sounds and movement, without adventitious sounds, form the most favorable presentation. The presence of adventitious sounds increases the gravity of the case. The finer the rales heard the better for the patient. Coarse bubbling rales are eminently unfavorable for him. The greater the lack of percussion resonance

the worse is the prognosis. Localization of the signs at the apex alone carry the more favorable prognosis. Basic tuberculosis of primary origin is more favorable. Multiple initial lesions have a bad prognosis. When tuberculosis attacks the apparently full-blooded it must receive an unfavorable prognosis. Deformity of the chest causes our prognosis of tuberculosis of the lungs to be more unfavorable. Tuberculosis of the lungs attacking those who are the subjects of tuberculous glands is generally very slow in its progress and favorable to treatment. The author strongly discountenances any attempt at the dispersion of such glands by means of iodine applications; but when the surgeon cannot deal with them, nuclein acts well when given by mouth. Pleurisy with serous effusion preceding an attack of tuberculosis would seem not to increase the gravity of the tuberculosis. Empyema, when followed by tuberculosis, increases very greatly the gravity of the latter disease. Precedent pneumonia does not appear to have an unfavorable influence on an engrafted tuberculosis. Tuberculosis of the lungs following that of the urinary organs is not increased in gravity by the infection of the latter. [J.M.S.]

11.—Williams treated a **rodent ulcer** on the left side of the nose of a woman of 70 years of age which had resisted other remedies; **resorcin** ointment healed it in about 2 months. [W.S.N.]

12.—Busfield reports a case of **rodent ulcer** of remarkable size, developing from a sebaceous cyst in a man of 70. The ulcer involved most of the right side of the face, and in places the bone was exposed as also was the right eye. [W.S.N.]

13.—Steele reports the case of a man, aged 50 years, who used **inhalations of oxygen** for **angina pectoris**. For 6 weeks he has had no attack. [J.M.S.]

1.—Maguire divides **tuberculosis** into 3 stages: invasion, progress, and result. In the first, the object of treatment is complete cure; in the second, we hope for arrest, but in the third the outcome is exceedingly dubious. Nevertheless, he mentions a case that had attended the Brompton Hospital for 15 years, having had, during the entire time, the physical signs of cavities in the lungs, although her general health remained excellent. The earliest changes are lack of resonance, and deficiency in the breath-sounds. Later there is retraction of the apex of the lung, and the prognosis becomes distinctly grave, especially if rales are present. Fine rales are not so serious as coarse rales. Very rarely tuberculosis commences in the base of the lung, and in these cases the prognosis is more favorable; if, however, the dis-

ease is secondary to pneumonia, or occurs as a lesion secondary to tuberculosis elsewhere, the prognosis is very grave. When it commences in the middle lobe of the right lung, it is usually rapidly fatal, and this is equally true if the middle lobe is invaded by a secondary lesion. Multiple lesions are, of course, very unfavorable, particularly if they are all primary, because under those circumstances they indicate the intensity of the tuberculous poison, and the vulnerability of the patient. Among the more unfavorable types of tuberculosis is one that Maguire names **multiple pleuritic onset**. The patient complains of malaise and irregular aches and pains. A careful physical examination reveals a few slight pleuritic rubs, otherwise the physical signs are often negative. In these cases a severe hectic fever develops, and the patient quickly dies. Another fatal form is **emphysematous**. The patient complains of cough, and a sense of suffocation. The physical signs are those of emphysema, but there is rapid emaciation, often slight fever, and then rapid breaking down of both lungs. In general Maguire believes that if the symptoms are out of all proportion to the physical signs, the prognosis is bad. He mentions as an instance of this a type in which the patient remains in bed for a long period of time, suffers from emaciation and extreme weakness, but has none, or only slight cough; there may be a few rales at the apex, and a few streaks of blood in the sputum; then suddenly there is a furious outbreak of pulmonary tuberculosis and early death. He suggests for this the name of **latent pulmonary tuberculosis**. Among his other observations is the fact that anemic patients usually do better than florid patients. Any deformity of the chest is rather unfavorable. In patients with tuberculous glands, other forms of tuberculosis run a very slow course. In such cases the glands should be excised in order to get rid of an added focus of infection. Pleurisy and pneumonia preceding an attack of tuberculosis render the prognosis very grave. The pleuritic effusions, however, occurring in the course of pulmonary tuberculosis should not be removed unless they cause mechanical disturbances, as they appear to have a favorable influence upon the pulmonary condition. Tuberculosis commencing in the urinary tract usually remains localized for a long period. A study of 22,000 cases leads him to conclude that heredity does not play such an important role as has hitherto been believed. [J.S.]

2.—Bennett advocates simple **aspiration** in the treatment of certain **chronic abscesses**. In general the best plan is free incision and scraping, followed by suturing or drainage according to the case. But when working among poor people in unsanitary surroundings with inadequate means for obtaining asepsis and difficulty with regard to dressings, such extensive operations are sometimes impossible for the general practitioner. Bennett does not advocate the indiscriminate use of aspiration in chronic abscesses to the exclusion of free incision and scraping, but he believes that in many cases it may be adopted without interfering with the patient's ordinary avocation and it may be used with safety in some cases in which more radical means are dangerous. Certain cases which are not cured by aspiration are reduced in size so that a radical operation is reduced from a measure of great severity to one of comparative slowness. In tuberculous disease of the lymphatic glands aspiration is not recommended under any circumstances, but 2 cases of disease of the hip-joint with large abscesses are reported, in 1 of which improvement resulted so that a slight radical operation was necessary, while in the other the disease was entirely cured. A case of psoas abscess was also successfully treated. Absolute surgical cleanliness is of the greatest importance. In performing aspiration the needle should be withdrawn the moment any sign of blood shows itself. The abscess may be aspirated repeatedly and should not be allowed to regain more than half the size before aspiration. [M.B.T.]

3.—Wright has undertaken an elaborate series of investigations in order to determine the **bactericidal power of the blood**. To accomplish this, he has devised the following ingenious method: Measured quantities of blood-serum in greater or less dilution are mixed in capillary tubes with a gelatin culture of the microorganism which has been incubated for 1 or 2 days. Control tubes are then filled with an equal amount of the culture, and some indifferent fluid, both are incubated, and the colonies counted at the end of

1 or 2 days. The capillary tubes are made in the ordinary manner, and are then graduated by filling them with a solution of colored fluid, from some capillary pipet holding about 5 cmm. such as that supplied with Gowers' hemocytometer. This column of the fluid is then allowed to flow from mark to mark until the capillary tube is graduated. The blood may be obtained from a finger, and is allowed to clot, and then centrifugated. Ordinarily it is desirable to dilute it considerably in order to test the maximum action. The mixture of blood serum and culture is then drawn into capillary tubes, one end of each being sealed. An ingenious device is described for mixing the 2 fluids without producing air-bubbles. The tubes are examined between two glass slides, the space between which has been filled with Canada balsam or cedar oil. The results of this method applied to typhoid fever were as follows: In 50 normal bloods a two-fold dilution sufficed to kill the bacillus, and in 22 cases separately tabulated, a tenfold dilution was sufficient; and in 15% bactericidal effects were complete in forty-fold dilutions. This bactericidal power diminishes very rapidly after the withdrawal of the serum. The addition of antityphoid serums of high agglutinative power to normal blood, caused almost complete loss of the normal bactericidal power. In guineapigs inoculated with serum, cultures produce after a time an increase in the bactericidal power. [J.S.]

5.—Ten cases of **movable kidney** are reported and some conclusions are drawn from the histories. Davy divides these cases into 2 distinct classes; the first in which the kidney can be felt and can be replaced to its usual site; the second group in which the tumor when found cannot be replaced. Under the latter condition it is often very difficult to make an accurate diagnosis. Hydrosalpinx, enlarged gallbladder, hydatid disease of the liver and a liver produced by tight lacing must be considered. In the more favorable cases the symptoms seem to subside when the patient wears an abdominal belt with an inflation-pad in the region of the kidney in front, which keeps the kidney from constantly shifting its position. In some cases the belt is of no avail, the symptoms continue and the patient's life is rendered miserable. In such cases operation should be recommended. One case is reported in which nephropexy was performed and the result was only partially successful. [M.B.T.]

6.—A man of 24, with **tuberculosis**, went to South Africa, where he did not improve; upon his return to England he was extremely emaciated, there was cough, and profuse expectoration filled with tubercle bacilli; there was a cavity in the left lung, consolidation of both apices, and ulceration of the larynx. The temperature was high. After failure to improve in a hospital he was sent home, where he carried out the **open-air treatment**. In 5 weeks he had gained 5 pounds, and was then sent to an institution where the open-air treatment was continued. In the course of some months he had increased very considerably in weight, the cough and night-sweats had ceased, there was very slight expectoration, and the patient was apparently cured. A few tubercle bacilli, however, could still be found in the sputum. [J.S.]

7.—Eddington describes his experiments upon the prevention or cure of **South Africa horse sickness**. The disease is apparently contracted by grazing during the night. It is exceedingly severe, killing, in some regions, as many as 90% of all the horses annually. A single attack protects against all others. It does not appear to be directly contagious from horse to horse; the symptoms consist either of enormous swelling of the head with dyspnea just before death, or the dyspnea without the swelling. The cause of death is a serous or gelatinous exudation found in the interlobular spaces of the lung, in the subpleural and subpericardial tissues, and sometimes in the subcutaneous tissues. This fluid inoculated into other animals does not invariably cause the disease, but the blood of an infected animal will always produce the characteristic symptoms. The disease so communicated is similar in all respects to the original spontaneous form. Injection of the filtered serous exudation does not convey immunization. Various animals besides the horse were tested; it was found that the donkey is much more resistant, none of 12 dying; only 4 of 21 cattle died, and none of 17 goats. Sheep are slightly susceptible, and rabbits, guineapigs, rats, and mice not at all. The blood from a donkey which had been inoculated produced very variable results. As a result of a number of experiments,

Eddington found that protection could only be obtained when there was a definite reaction, that the susceptibility of horses varies very greatly, that it was difficult to attenuate the virus with any degree of accuracy, and that the most important thing was to obtain a virus fixe. Animals were gradually immunized or "salted" by injecting increasing doses of the blood. The serum from these animals had neither protective nor curative influences. A standard virus was prepared, however, by mixing 1 ccm. of virulent blood with 100 ccm. of blood from an immunized animal. By rendering the dilution less, doses of increasing severity could readily be given. By this method 16 horses were immunized with the result that 11 were "salted," that is, resisted a large dose of virulent blood, and 5 died. Another series of 7 were inoculated with slightly varying doses, and 5 were protected; and the third of a series of 12 horses treated with somewhat stronger dilution, all giving characteristic reactions. The "salted" animals, when inoculated, are capable of conveying the infection to others; although they exhibit no symptoms of the disease, their condition representing one of toleration. [No results of bacteriologic or other investigations regarding the nature of the disease, are given. J.S.]

8.—A number of cases of **peripheral neuritis** which have been observed in Manchester, present certain peculiarities that distinguish them from alcoholic neuritis. The paresthesia are intense, and often painful. There is inflammation of the conjunctivas of the eyes and nose; there is often a history of nausea and vomiting, and the paralysis is frequently extreme. There is considerable pigmentation of the skin, and occasionally various eruptions, such as herpes, papules, etc., desquamation, thickening of the skin, changes in the nails, and sometimes boils. Colic is very unusual; there is no disturbance of the urinary system, and the apparent cause is the consumption of beer, although a large proportion of the cases did not drink to excess. Analysis of the beer showed the presence of arsenic. The cause of the contamination of the beer was found to be in the sugar, and it was introduced with the sulfuric acid used in its manufacture. A sufficient quantity was found to account for chronic arsenical poisoning. [J.S.]

9.—Celli describes the following methods of **preventing** the occurrence of **malaria**: First, ointments applied to the skin, calculated to prevent the mosquitos biting, and second, the mechanical protection of houses. This is best accomplished by the use of wire gauze instead of the ordinary netting, and a porch built of this gauze in which the people can live with safety in the open air. In addition, all cases that have been infected are thoroughly cured. The results of this method were simply extraordinary. Even in the most dangerous districts, large numbers of the employees of the railroads passing through these districts, spent the entire summer without contracting the fever, and their wives and children were similarly fortunate. Even the wretched habitations of the peasants, when carefully protected, were found to fail to develop their usual quota of cases of the disease. [J.S.]

10.—A man who had been suffering two days with symptoms of acute **intestinal obstruction** was operated upon, but the obstruction was not found. Two days later, death followed. At the necropsy the upper part of the left chest was occupied by a collapsed lung, while nearly the whole side was occupied by omentum and a knuckle of the transverse colon which had escaped through a **slit in the diaphragm**. This slit had been caused 4½ months previously by a fragment of shell which had penetrated the chest and which had not been removed. [M.B.T.]

11.—Wilson reports 2 cases of men who died rather suddenly with dyspnea, and at the autopsies the only changes found were pleurisy on the left side, and pericardial effusion. [J.S.]

13.—Two cases of **intussusception** are reported in which operation was performed. In the first case a female child 3 months and 2 weeks old had been taken with symptoms of intussusception 2 days before admission to the hospital. Celiotomy was performed and a double invagination was reduced. Reduction was at first easy, though there was difficulty in unfolding the last three-fourths of an inch of intestine. The child died 4 hours after the operation, while vomiting, when apparently she had rallied satisfactorily from the operation and all was going well. In a second case a

woman of 29 was operated upon for the relief of an intussusception of the small intestine caused by an intestinal lipoma. Her illness had begun 5 weeks previously with severe pain, diarrhea, and vomiting. The acuteness of the attack subsided, but she was troubled with vomiting every day, which became worse 10 days before admission, subsiding and again becoming worse the day before admission. After reducing the intussusception in the usual manner a firm nodular tumor as large as a hen's egg was felt in the bowel. A longitudinal incision was made opposite the mesenteric attachment and a pedunculated fatty tumor was removed. Bleeding was arrested and the mucous membrane was sutured. An uneventful recovery followed. [M.B.T.]

5. The Prevention of Nausea and Vomiting during Anesthesia. LOUIS J. HIRSCHMAN.
6. Strangulated Inguinal Hernia, Containing the Cecum and Appendix. HENRY PERKINS MOSELEY.

1.—Thienhaus, in discussing the necessity for radical therapy of uterine fibroids, says that myomatous growths of the uterus, like foreign bodies such as gallstones, bullets, etc., so long as they give rise to no symptoms whatever are by no means subjects for any interference. Though symptomatic and palliative treatment of fibroids with drugs, electricity, or mechanical means, may be beneficial in well-selected cases, there is no certain way of removing them except by surgical operation. Radical operative treatment is indicated in cases: 1. In which we find, or can suspect, carcinomatous or sarcomatous degeneration in the fibroid itself. 2. In which fibroids are complicated with malignant degeneration of the uterus or adnexa. To determine this condition with certainty it may be necessary to have a careful microscopic and macroscopic examination, by an expert, of tissues obtained by curetment. 3. Operation is absolutely indicated in cases of torsion and rotation of the myomatous uterus, because of the danger of gangrene and septic peritonitis. 4. In cases which are of such enormous extension that they threaten life by pressure on the diaphragm and on the other abdominal organs. 5. Cases which produce hydronephrosis, or even complete anuria by pressure on the ureters, sometimes with inflammation of the kidneys, pyelonephrosis, etc. 6. Cases, which by the location of the origin of the fibroid, or by retroflexion of the uterus, produce grave symptoms of incarceration in the small pelvis, such as serious neuralgia, symptoms of severe dysuria in connection with ischuria paradoxa and coprostasis. 7. In cases in which uterine fibroids grow quickly, particularly near the climacterium, radical therapy has to be employed. In many of these we find cystic, myomatous, or sarcomatous degeneration. 8. In cases of uterine fibroids in which suppuration has occurred, or which are gangrenous, or are in a state of becoming gangrenous after partial or total inversion of the uterus, thereby causing great pain by labor. 9. Uterine fibroids, complicated with umbilical hernia, pyosalpinx, ovarian cysts, pelvic cysts, tuboovarian abscesses, abscesses in the broad ligament, phlebitis. 10. Weakening menorrhagias and metrorrhagias produced by fibroids, which give the patient the waxlike appearance that of itself enables us oftentimes to make a probable diagnosis at first sight, are further indications. 11. Fibroids, which, at the end of pregnancy, and at the beginning of labor, are obstacles to childbearing. 12. More seldom it may be found necessary to operate during pregnancy. All surgeons will probably agree upon these 12 points, but in cases in which there is no great immediate danger to indicate surgical treatment, but in which there exist conditions in the patient

which make the removal of the growths desirable, the question of operative interference cannot be settled by discussion, but must be left to the individual discretion, and must be treated individually, as well from the standpoint of the patient as from that of the surgeon. [W.K.]

2.—Woodward divides the derangements of the organs of vision, which may be attributed to autoinfection or autointoxication into 2 classes: Those that are purely functional, and those in which there is some demonstrable structural lesion. The first occur in such cases as neurasthenia and migraine, where, by correcting some slight optical error and then treating the gastrointestinal system, the patient is promptly cured; but not so with the second class, where this organic change in the eye is accompanied with rheumatism, gout, or Bright's disease. These rarely improve, and operative treatment is only temporary. Intracocular hemorrhages, although, at times caused by slight pressure, often give rise to quite extensive trouble, and care should be taken not to confound them with *muscae volitantes*. [W.S.N.]

3.—Pooley in the treatment of trachoma finds that the operation of expression gives the best results, and relapses under this method are not so likely to occur, but it has its limits too, and proper after-treatment must be carried out in conjunction with it. [W.S.N.]

4.—Robinson has made a study of cysts of the ligamentum latum, in 100 cases, and finds their kinds and location as follows: 1. Supraoviductal in 7%. 2. Of the diaphragmatic band in 65%. 3. Cysts of the mesonephritic uriniferous tubules in 38%. 4. Of the mesosalpinx 25%. 5. Hydroparasalpingeal cysts in 25%. 6. Cysts of the mesonephritic duct (Gartner's duct) in 30%. 7. Lymph cysts of the ligamentum latum in 25%. 8. Chiari's cysts he was unable to confirm, not being able to study any. 9. Kobelt's cysts occurred in 45%. 10. Cysts of the proximal end of the oviduct in only 2%. 11. Cysts under the perisalpinx are not easy to distinguish and no numerical estimation was attempted. 12. Cysts, fragments of the adrenals in the ligamentum latum, no estimation made. 13. Cysts of the fimbriae occur less frequently than is supposed. The macroscopic cysts in 100 subjects constituted 90% and their division is as follows: A. From the pronephros. 1. Hydroparasalpingeal cysts, 25%. 2. Lymph cysts 25%. 3. Cysts (hydatid) of Morgagni, 6%. 4. Cysts of the proximal end of the oviduct, 2%. 5. Cysts of the fimbriae, 2%. 6. Cysts under the perisalpinx none. 7. Chiari's cyst, none. B. From the mesonephros. 8. Kobelt's cysts in 45%. 9. Cysts of the mesonephritic uriniferous tubules in 38%. 10. Cysts of the mesonephritic duct in 30%. 11. Cysts of the mesosalpinx in 25%. 12. Supraoviductal cysts in 7%. [W.S.N.]

5.—Hirschman has found that the administration of chlorotone gave good results in preventing nausea and vomiting during anesthesia. To women he administered 10 grains, to men, 15 grains, about a half hour before operation, and in a series of 50 cases where 80 received this drug only 3 suffered from nausea, and 1 vomited; while of the other 30 cases, 24 vomited, and 19 of them could not retain food the following day.

Medical Record.

December 15, 1900. [Vol. 58, No. 24.]

1. Wounds of the Heart, with a Report of 17 Cases of Heart-Suture. L. L. HILL.
2. Internal Hemorrhage, the Result of Traumatic Rupture of Adhesions due to Acute Appendicitis, with the Report of a Case. LOUIS J. LADINSKI.
3. Insanity, its Causes; Is there in Woman a Correlation of the Sexual Function with Insanity and Crime? MARY DIXON JONES.
4. Analgesia in Children by Spinal Injection, with a Report of a New Method of Sterilization of the Injection Fluid. WILLIAM SEAMAN BAINBRIDGE.

1.—Hill reports 2 cases of wounds of the heart and a series of 17 others in which the heart was sutured. His first was a girl, 8 years of age, whose heart a needle had penetrated at the level of the fifth interspace. It was simply extracted under cocaine, and recovery followed. The second, a colored man of 28 years, stabbed in the fourth interspace a little to

the right of the left nipple line. The pulse was poor and suffering intense, the pericardium was enlarged and evidently it was rapidly filling with blood, and pressing upon the heart's action; this was proved by operating. Great relief and general improvement followed and the case ultimately recovered, although complicated by a traumatic pericarditis. In suturing the heart the same needle is used as in intestinal operations. Silk is the best material, and it should be inserted and tied during diastole. The question of administering an anesthetic is still unsettled, but under no circumstance must the patient struggle. The other cases reported were collected by Giordano. The chief danger in wounding the heart is the involvement of the coronary artery, the injuries to the auricles are more fatal than the ventricles, and to the apex least of all. Wounds inflicted during systole are more fatal than during diastole and perpendicular cuts more than diagonal ones, and after these wounds heal the cicatricial tissue is not as firm as the heart-muscle and cases have been reported where it has ruptured after healing and death following. Blows over the heart are most apt to cause rupture after a full meal.

2.—Ladinski reports a case of **traumatic rupture of adhesions about the appendix resulting in almost fatal hemorrhage**, in a boy of 11 years, caused by a fall. The great difficulty was in the diagnosis. The appendix was bound down in a U shape, and the jar ruptured the meso-appendix for about $\frac{1}{2}$ inch. [D.L.E.]

3.—Jones gives a general discussion of the question of the relation between the various phases of the sexual function in women with insanity and crime. She insists that the only relation between menstruation, pregnancy, parturition, and other similar conditions is, that if the individual is already predisposed to psychic neurosis, the slight extra strain that any one of these conditions causes may induce the onset of insanity. She strongly opposes Clouston's divisions of insanities. She does not even believe in syphilitic insanity, nor in the possibility of a uterine and amenorrheal insanity. She considers there is no such thing as an insanity necessarily belonging to the puerperal state, and considers that it is not scientifically accurate to speak of puerperal insanity. In general, she insists that all the sexual functions are physiologic, and that she does not believe that physiologic processes themselves, unless acting in a person of evil construction, will cause any pathologic conditions. [D.L.E.]

4.—Bainbridge has used **spinal injections of cocaine to produce analgesia in children**, the youngest being only $2\frac{1}{2}$ years old, and on this one he performed, first an osteotomy and tenotomy in which analgesia was produced by the injection of 7 m. of a 1% solution between the third and fourth lumbar vertebrae. Again, in a few weeks he injected the same amount of eucain and redressed the leg without the least bit of annoyance to the child. Then the week following this, another operation for talipes was performed under cocaine. This time 10 m. were injected. After these operations the child showed some slight reaction, but during the time they were performed it played with a doll. One of the children, a girl of 4 years of age, became frightened and caused some annoyance, but analgesia was complete. In most of the cases there was very little reaction, except in one, a boy 7 years of age and poorly nourished, who for a few days afterwards remained in a stupor, and another, an epileptic boy of 9 years of age, who in the first 16 hours had 3 fits. The headache in most of them was easily controlled by acetanilid and caffeine. His method for sterilizing the cocaine is to pour over it about a dram of ether and allow it to evaporate, and then dissolve it in boiled water.

6. A Note Concerning the Treatment of Influenza by the Employment of Hydropathy. E. L. SHURLY.

7. Infantile Grip with Unusual Temperature Range. L. E. LA FETRA.

1.—Jacobi discusses the various methods or the treatment of **influenza in children**. He believes that prophylaxis is almost impossible as the disease is so widely spread during epidemics and so readily communicable. There is no specific, although many drugs have been so recommended. Cold water is not indicated in cases of high temperature, but a warm, not a hot, bath often soothes muscular pain and restlessness. He appears to have reached no positive conclusion regarding the value of quinin. In severe cases of vomiting the patient should be fed by the rectum; the temperature can best be reduced by some of the coal-tar antipyretics, particularly antipyrin; acetanilid should never be employed. Caffein is the most efficient stimulant for heart-failure; spartein is also useful. He calls attention again to the value of Siberian musk, and states that by its use he has saved the lives of several apparently hopeless cases. [J.S.]

2.—Butler mentions the following types of **epidemic influenza**. 1. The respiratory, with severe cough and slight physical signs in the lungs. 2. The nervous form, with severe headache, pain in the back and limbs, and prostration. 3. The gastrointestinal type, with nausea, vomiting, abdominal pain, and diarrhea. 4. The typhoid or febrile variety, with delirium, dry brown tongue, tympanites and recurrent chills. The sequels are bronchopneumonia, pleurisy, abscess and gangrene of the lungs; edema of the lungs and enlargement of the bronchial glands; abnormal quickness of the pulse, irregularity of the pulse, and weakness of the heart's action. There may also be melancholia or mania with migraine, and in rare cases violent meningeal symptoms. A neurasthenic state also occurs; there may be enlargement of the spleen, various forms of nephritis and suppuration in various parts of the body. The most reliable diagnostic sign is the discovery of the bacillus. This requires the assistance of an expert. The 3 diseases most likely to be confounded with influenza are typhoid fever, cerebrospinal meningitis, and bronchopneumonia. [J.S.]

3.—Mosher calls attention to the fact that an attack of **influenza may cause the development of latent forms of nervous disease**, and thus give rise to the belief that it has been the cause of such conditions as paralysis agitans and systemic degenerations. The nervous symptoms accompanying the attack may be in the peripheral nerves, giving rise to severe pains in the back and limbs, or symptoms of polyneuritis followed by degeneration of the muscles. Various affections of the heart also occur, particularly bradycardia. He reports the case of a woman, about 40 years of age, who had a severe attack followed by dyspnea, and then by numbness over the entire right half of the cranium; this region was analgesic and hypesthetic, and there was loss of hearing in the right ear, followed by loss of smell and tactile sense in the right nostril. There was then paresis of the respiratory muscles of the left side; there were various spasmodic and clonic movements; Cheyne Stokes respiration; photophobia, and temporary stupor. An injection of morphia relieved all the symptoms, and she finally recovered completely. [There seems sufficient reason to believe that a hysterical element was present in this case.] He also reports the case of a girl, 14 years of age, who had severe delirium with meningeal symptoms, and who was finally regarded as insane. She developed symptoms of consolidation at the apices of both lungs, then severe decubitus over both hips, but finally she recovered completely. Mosher concludes that the toxin of influenza attacks the nervous system, causing various affections of the peripheral nerves, and various types of insanity. The latter are due probably, in great part to vital depression. [J.S.]

4.—Lartigau, in the course of a brief description of the peculiarities of the **bacillus of influenza**, mentions the degenerative forms observed by Grassberger and himself. He speaks of the extreme susceptibility of the bacillus to various destructive agencies, the favorable effect exerted upon cultures by *Staphylococcus pyogenes aureus*; the fact that they do not develop in the lower animals, even monkeys; the inability to produce immunity; the fact that the bacilli may

persist in the sputum for weeks after the abatement of the symptoms, and the methods of bacteriologic diagnosis, and concludes: "If the sputum contains an almost pure culture of a very minute bacillus, which takes the stain faintly when compared with the other bacteria present, and which is decolorized by Gram's method, it may be assumed that the case is one of influenza." To obtain cultures the mouth should be washed with sterilized water, the exudate obtained from the pharynx with a swab and then rubbed on solidified serum containing hemoglobin. [J.S.]

5.—Wilcox makes the following suggestions for the **treatment of influenza**: When the disease attacks the respiratory system it is important to give a stimulating expectorant such as ammonium carbonate in 5 to 10 grain doses as often as may be necessary. If stimulants are required, strychnia may be employed. If the convalescence is tardy, carbonate of creasote is especially valuable. In the gastrointestinal form, a preliminary dose of calomel should be given, followed by some form of intestinal antiseptic by doses of bismuth salts. High intestinal irrigations aid much in eliminating the toxins. In the neuromuscular type it is necessary to relieve the pains. This can best be done by a combination of the coal-tar products guarded by caffeine. Morphin produces bad results. The diarrhea that often occurs should not be treated. Warm baths frequently relieve the pains and keep the skin in a good condition. [J.S.]

6.—Shurley recommends the more general employment of hydrotherapy in **influenza**. This acts partly by promoting elimination, and in the early stages should be used in the form of persistent hot water baths, the steam bath, or the hot water pack. Quinin is also useful. It is not always desirable to introduce steam directly under the bedclothes. If the temperature is very high, a cold pack may be employed in order to allay pain. Paregoric or opium is the most satisfactory drug. Phosphorus seems to act favorably during the convalescent stage. [J.S.]

7.—La Fetra reports a case of **influenza** in a girl baby, 13½ months old, in which an excussion of 10.5° in 24 hours was noted on one occasion and 9.5° on another. Her removal from home in which the infection was present was followed by prompt recovery, and by an equally prompt relapse on her return home. La Fetra believes that the sulfur fumigation that was employed was inefficient, and recommends formaldehyd. [J.S.]

2. Cases of Acute Oral Inflammation. JOHN C. MUNRO.
3. The Results of Operations on Varicose Veins. J. B. BLAKE.
4. A Contribution to the Therapeutic Action of Heroin. BERNARD LAZARUS.

3.—Blake reports 11 operations for **varicose veins**. He concludes that the radical cure of varicose veins by dissection is not successful in every case. To obtain successful results the cases must be selected, and sometimes palliative treatment proves more satisfactory. Conditions which militate against good results are old age or an extremely debilitated condition, excessive and extensive varicosity, and occupations which favor the development of varicose veins. Cases which may be cured by a thorough and careful operation are local varix, even of marked prominence, extensive varix limited to a single venous stem, varicosities which are a bar to civil or military examinations in cases in which the development of permanent varicosity was at least partially due to more or less removable conditions, such as flatfoot, tight garters, etc. Operation, even if not entirely successful, will usually relieve such complications as thrombosis, hemorrhage, and ulceration. The conditions which follow unsuccessful operations are pain in and about the scar, general swelling, and tenderness of the leg, the development of varicosities above or below the scar. In all cases general systemic treatment as well as local treatment should be prescribed, together with exercise and the avoidance of continued upright position whenever possible. Cure of symptoms does not necessarily mean removal of all visible varicosities. Comparison of relative methods of multiple

ligation, and continuous dissection must be based upon a larger number of cases than are here recorded. [M.B.T.]

4.—Lazarus reports briefly 9 cases out of a series of 52 that he had treated by the use of **heroin hydrochlorid**. The ill effects have been few and have only been noted when large doses were used, such as ½ grain. He considers the drug a most valuable aid to the medical profession. Its range of application, while originally confined to the treatment of respiratory affections, has been much extended by later observations. In pulmonary affections accompanied by coughs, he would rank it as a specific, while its analgesic qualities in neuralgia and its antispasmodic effect in asthma and whooping-cough have been so well established as to entitle it to a prominent place in the treatment of these affections. 9.—Packard, while performing a necropsy on a woman, who died of sepsis caused by a **suppurating hydatid cyst**, found a **tænia favopunctata** in the small intestine 2.5 cm. above the iliocecal valve. Just before the woman died she passed a segment 16.5 cm. long. When the worm was found it was still living and 15 cm. from the lower extremity it was tied in a tight knot. Its total length was 27 cm.; the color was white, of a yellowish cast, the head was distinctly black at the tip and was flattened from side to side, measuring 1 mm. by 0.5 mm. The pigment was deposited in the shape of a four-leaf clover and each division represented a sucking disc; there was no cupping. The neck was 1 mm. long by 1.5 mm. in width. At a distance of 1.5 m. transverse striations were seen, evidently marking the divisions between the proglottides. The following segments resembled those passed during life, and tapered from the neck 3 mm. wide and 2 mm. long, to 7 mm. wide and 1 mm. long; one edge was 1 mm. thick, and extending toward the center were dark lines ⅓ mm. in thickness and 3 mm. in length; these were the uteri and contained eggs. The worm is very rare in the human subject, this being only the sixth case reported. [W.S.N.]

1.—**Gunstock deformity of the humerus** consists in marked permanent adduction of the forearm, most apparent when the elbow is in full extension. Clinically the most important feature is the abrupt movement made by the forearm toward the ulnar side as the limb approaches full extension and a peculiarly ungraceful appearance of the limb in this position. Flexion, extension and rotation are usually normal. The immediate cause is a change in the relations of the transverse axis of the elbow-joint to the longitudinal axis of the humerus, a change by which its normal inclination looking downward and outward is changed to one looking downward and inward. Stimson has collected several specimens and skiagrams which throw some light upon the cause of this condition. They show that the deformity due to undoubted fracture and ascent of the internal condyle which has previously been considered the almost exclusive cause of this deformity are almost unknown. In all the joints one point stands out prominently; the unbroken line of the articular surface. This proves that the line of fracture does not extend through it; the cause of the deviation of the axis of the joint is not ascent of the internal condyle or descent of the external condyle, but a twist of the entire articular process. Another point is that the displacement in all is angular, pivoting on the inner side just above the internal epicondyle. Experiments upon cadavers showed that in all the fracture was produced by forcible adduction of the extended forearm. Two forms of fracture resulted, one purely supracondyloid, the other, the line of fracture began on the outer side, at or close above the junction of the shaft and epiphysis and passed inward. In all, the periosteum remained in great part un torn. Stimson believes that it may be fairly assumed that in treating these fractures the displacement is usually corrected, but it recurs during the application of dressings or subsequently. The only agent which could produce it is the unsupported weight of the limb. Correction of the displacement could probably be easily made by pressure upward and outward against the olecranon in rectangular flexion of the joint or abduction of the fully extended forearm and maintenance of the latter position for a week or two. It should be combined with confinement to bed. He does not believe that full flexion of the joint could be trusted to correct the displacement or prevent recurrence because in all patients with a deformity free flexion of the joint was possible. As the deformity does not prevent the attitude, the attitude cannot prevent the deformity. [M.B.T.]

2.—Wood has collected 150 cases of **castration for hypertrophy of the prostate**. He finds that in 51.5% of the cases the prostate decreased in size and in many other cases there was improvement of the patient's general condition, relief of cystitis and return of normal micturition and other evidences indicating a decrease in size of the prostate. He believes that over 90% were benefited. In only 4.6% was there no improvement. The mortality was slightly over 80%. Even in fatal cases improvement was frequently noted. In a considerable number of fatal cases the kidneys were infected as the result of the enlargement, and a fatal result might have been prevented by proper treatment at the right time. Few instances of mental disturbances are reported. On the other hand, many instances of improved mental and physical vigor are noted. He found no change of voice or alteration of disposition which has been theoretically suggested as an objection to the operation. Wood has also collected 193 vasectomies for prostatic hypertrophy.

The prostate diminished in size in over 9% of these cases; there was improvement in micturition in 15%; cystitis was cured or relieved in over 6%, and residual urine diminished or disappeared in 50%; mental disturbance was noted in a few instances. In this respect the two operations were on the same footing. He believes that these figures give ample reason for advising and performing one of these operations in suitable cases. Brief abstracts of the cases which Wood has collected are given. [M.B.T.]

3.—Woolsey credits Championnière with the introduction of **massage in the treatment of fractures**. Immobilization only relieves pain from the movement of the fractured ends. It imperfectly restores the form of the part, does not favor repair of bone or restoration of function, but often causes scanty callus, delayed union or nonunion, and results in stiffness of joints, atrophy of muscles and disturbance of circulation. On the other hand, a certain amount of motion is favorable to repair of bone. Massage in addition to furnishing this prevents atrophy of muscles, reduces swelling and restores the circulation. There are certain contraindications to its use, such as the presence of large blebs, projecting fragments, great mobility, the tendency to reproduction of deformity, and in compound fractures. Woolsey sees no advantage in entirely discarding splints in the early period of treatment. Their use gives confidence to the patient and a sense of security that no displacement is likely to occur. Particular attention should be paid to the position of the limb, carefully reducing deformity and keeping it reduced, during massage, between the periods of massage, and when the limb is in a splint. If this is not possible from the onset after preliminary massage, plaster should be applied and kept on from 8 to 14 days. Then massage is commenced. The results in these cases are better as far as position is concerned, equally good functionally and nearly if not quite as quickly obtained as when massage is employed from the first. If after massage for some time position be imperfect or if after 3 weeks firm union has not taken place he advises using plaster for 8 to 14 days, though the functional result is thereby delayed. He believes that the treatment of fractures, particularly articular and periarticular fractures by massage and passive motion, gives the best and quickest result as to bony union and function of any method of treatment. [M.B.T.]

4.—A man, 32 years old, had typical **tuberculous arthritis** of the wrist which had begun about 2 years previously. The wrist-joint was excised through an incision on the dorsum of the hand extending from the radius downward between the second and third fingers. Taylor finds this incision very convenient, enabling all the bones of the wrist to be cleared out and the ends of the ulna and radius to be sawed off with less inconvenience than any of the older methods. The result obtained in this case was excellent. [M.B.T.]

5.—Mayo discusses the anatomy of the ileocecal orifice and states that in a number of abdominal operations recently he has examined the ileocecal coil with some care in order to estimate approximately the size of the ileocecal orifice and to determine its bearing on obstinate constipation. He finds that in most cases inspection will reveal no marked abnormality. The wall of the ileum may be invaginated by the finger into the cecum. He reports 2 cases of chronic constipation in which the ileocecal orifice was abnormally small and in which the pain and constipation were removed by a **plastic operation enlarging the caliber of the ileocecal opening**. He believes that there are certain cases in which organic or functional narrowing of the ileocecal opening is responsible for a train of symptoms of which pain in the region of the cecum without marked disease of the appendix and chronic constipation are important symptoms. The patients upon whom we operated both recovered and remained free from constipation and in greatly improved condition, one of them 15 months and the other 18 months after the operation. [M.B.T.]

6.—See PHILADELPHIA MEDICAL JOURNAL, Vol. V, p. 987.

7.—Kramer states that during the past 3 years he has been engaged in an investigation of **the nature of shock**. During these experiments he noted the phenomena produced by anesthesia on the circulatory and respiratory organs. Dogs were used for the experiments and the blood-pressure and cardiac contractions recorded by means of a manometer connected with the carotid artery. The movements of the thorax were recorded by means of a Berts exploring tambour attached to a strap of adhesive plaster

encircling the lower part of the chest. For control, certain unnarcotized animals were used. Ether was used as an anesthetic in all these cases. The central end of the crural nerve was stimulated. In the unnarcotized animals respiration increased in frequency, and the inspiratory effort was increased. Blood-pressure invariably rose if the animals were deeply anesthetized. There was absolutely no corneal reflex, and in most cases stimulation of the nerve was without effect upon the circulation or respiration. If the animals were partially anesthetized, the corneal reflex being present, respiration became accelerated and there was a fall in the blood-pressure a few seconds after beginning irritation of the nerve. He concludes from these experiments that severe vasomotor shock is more likely to follow operations done under partial anesthesia than those done under complete anesthesia. [M.B.T.]

3.—Stehman reports a case of supposed ureteral traumatism. After the removal of a large fibromyoma involving the breaking up of many firm adhesions, the abdominal dressings became decidedly moist from the escape of the urine. The usual tests were made to determine the location of the fistula, and, it being apparently in the ureter, the patient was anesthetized with a view of thorough examination. In dilating the tract a rent was made in the bladder and as the ureter could not be readily located, it was decided first to repair the rent in the bladder. This was accordingly done and thereafter no urine escaped from the fistula, but instead healthy granulation sprang up and it was soon closed. Evidently the defect was in the bladder, and this case demonstrates that the usual tests in determining whether urine escaping through an abdominal fistula is from the ureter or bladder are not always reliable, and do not possess the differential diagnostic value that the books teach.

[W. K.]

4.—Adhesions about abdominal tumors are sometimes so extensive and so firmly organized that they form the most important consideration in the operation. There are cases in which the walls of the cyst are so perfectly incorporated with the adjacent peritoneum and so adherent to the various organs, that none of the methods usually employed in breaking them up, are consistent with a probable maintenance of life, and the idea of removing the cyst must be abandoned and some other method of treatment pursued. Allaben reports a case illustrating this condition and a successful way of dealing with it. The patient, aged 31 years, gave a history indicating that the trouble dated back about 15 years. When the abdomen was opened a characteristic parovarian cyst about the size of a man's head was seen. This was punctured and more than 3 quarts of straw-colored fluid was discharged. There were extensive organized adhesions of the cyst-wall to numerous coils of the ileum, to the vertebral peritoneum, to the rectum, and to the floor and left side of the pelvis. Considerable time was spent in an effort to enucleate the cyst, but its walls were so adherent to the broad ligament and the surrounding peritoneal surfaces that these efforts were abandoned. The cyst was then drawn out as far as possible into the abdominal wound and stitched to the peritoneum in the lower angle so as to completely shut out the peritoneal cavity from the cyst cavity. The abdominal wound was closed to within 2 inches of the lower angle, a rubber drainage-tube having first been passed through the bottom of the cyst and out of the

vagina. A few strips of gauze were passed to the bottom of the cyst and allowed to protrude through the abdominal wound. Save for a rather rapid pulse for the first few days, convalescence was uneventful. After the operation the patient's health improved very much; she was free from pain and other unpleasant symptoms for 4 months, when she began to suffer pain on the opposite side, and vaginal examination showed a tumor of the right ovary. A second celiotomy was performed 6 months after the first, through an incision 2 inches to the right of the old cicatrix, and a multilocular ovarian cyst about the size of 2 fists was removed without difficulty. An examination of the site of the first tumor showed nothing present to indicate the existence of a former cyst. The matting of the intestines had entirely disappeared, and even the cyst walls had been entirely absorbed, leaving the parietal peritoneum free and smooth at the point where the cyst walls had been drawn out of the abdominal wound. Recovery from the second operation was smooth and the patient has since enjoyed good health with restoration of a normal menstrual function. By incising, emptying, and draining the cyst cavity we remove the cause exciting adhesions and induce conditions that ultimately work a permanent cure, and at the same time do not expose the patient to conditions prejudicial to life. [w k.]

5.—Stahl reports 3 cases of abortion treated by **curetage** to show the special distinct advantages which the finger possesses over the curet: 1. The superior advantage of the finger in recognizing the presence of foreign bodies in the uterus. 2. The advantage of shelling out the secundines intact with the finger instead of the usual morselling by the curet and forceps. Both of these advantages are of much importance. In reply to the objection that the tip of the finger cannot reach the fundus the writer claims that although the index finger may often be too short and unreliable, this is not true of the middle finger, which is longer, stronger, and swivels better, and he has never yet failed in its use. Abdominal pressure is necessary with the other hand. To the second objection that curetage is more painful than curettage, Stahl replies that it should not be so especially if chloroform is given. Even were it so, the security of knowing that the cavity is clear and that all danger has been removed, amply repays for the slight transient discomfort produced by the introduction of the half hand into the vagina. It is only a clumsy operator who is brutal, nor is such awkwardness a feature of digital manipulation alone; for a clumsily handled instrument is far more efficacious in inflicting pain than is the finger. [W.K.]

The Journal of Mental and Nervous Diseases.

6. A Case of Hysterical Aphonia in a Grand Mal Epileptic. L. PIERCE CLARK.

1.—Burr reports the case of a woman of 36, who was brought to the hospital in a semicomatose condition. She weighed about 300 pounds, and the excess of flesh was distributed chiefly in the form of pendulous masses on the arms, thighs, and abdomen. She could not move the limbs, excepting slight flexion of the fingers; she was sensitive to pain; the reflexes were absent, and there was marked optic neuritis. This condition had lasted about 2 years. The coma increased and death occurred. At the autopsy the fat was found to be fibrous; there was interstitial neuritis, and the thyroid gland contained a concretion, and there was considerable colloid degeneration. A glioma occupied the position of the pituitary body. There was also acute parenchymatous nephritis, and sclerosis of the ovaries. The lesions correspond with those found by Dercum in his case which came to autopsy. In both instances there was **disease of**

the thyroid, but Burr's case is rendered more interesting by the simultaneous presence of a lesion of the pituitary. He does not believe, however, that we are yet in a position to indicate with precision the pathology of the disease. [J.S.]

2.—Donaldson has studied the relation and size between the axis cylinder and the ganglion cells of the spinal cord in white rats. He found that a close relation between the cross-section of the nerve-fibers and the side of the cell exists, but that both increase more slowly than the total weight of the animal. The nerve-fibers of large caliber do not necessarily have the longer course in rats, but apparently have a more extensive distribution. In the discussion that followed this and other papers upon the neuron, Putnam urged that the cell-body does not store impressions. Langdon believed that when we understand the neuron theory more perfectly it will be possible to obtain practical results in therapeutics. Van Gieson urged that the neuron theory was now quite firmly established; he expressed a general agreement with the retraction theory, but did not believe that the protoplasmic processes had amoeboid movements. Darcum also advocated the retraction theory as a working hypothesis; Collins, on the other hand, did not believe that the retraction theory was at present worth serious consideration. [J.S.]

3.—Wilder, in making a second report, at an interval of 6 years, upon the brain of a suicide, stated that he was convinced by careful study that he has been in error in describing 2 central fissures in the left hemisphere; the second fissure being an unusually long and complete postcentral. [J.S.]

4.—McBride reports 2 cases of rigidity of the spine. The first commenced at about the age of 20 with severe pain in the left great toe; then the left hip began to grow stiff, and, at the age of 30, the spine. Ultimately the left arm, and then the right arm became rigid, and the entire spinal column almost immovable. Excepting the pain in the great toe, he had not suffered throughout the course of the disease. Sight gradually failed in the eyes, and hearing was also imperfect at the time of the examination. The second case, a man, had a severe fall at the age of 33; subsequently the neck became stiff and painful, and this was followed by weakness in the arms, wasting of the muscles, and wasting of the muscles in the legs; there was slight pain over the fifth cervical vertebra, all the reflexes were greatly exaggerated, and there was ankle-clonus. The second case was probably one of traumatic pachymeningitis. [J.S.]

5.—Bonar describes the case of a Jewish girl of 17, who had always been extremely thin, and unable to close her eyes completely. At the age of 16 she discovered that she was unable to raise her hand to her head; it was then found that all the muscles of the right shoulder were atrophied, and also some of the muscles in the back and in the face, the orbicular and buccinator muscles. The muscles of the hands and forearms were unaffected. The case represents the facio-scapulo-humeral type of progressive muscular dystrophy, originally described by Dejerine and Landouzy. [J.S.]

6.—Clark reports the case of a German, who at the age of 25 commenced to have epileptic attacks; after these attacks he would sometimes have a temporary aphonia and whisper-speech would persist for 6 days. From time to time this condition occurred after attacks of petit mal, and finally it occurred spontaneously. A diagnosis was, therefore, made of hysterical aphonia. [J.S.]

4.—Hamill reports the case of a boy, aged 6 years, whose family history gave evidence of acute articular rheumatism and heart disease. Since an attack of measles in January of the present year, the patient has had a short, dry, hacking cough by day, with nervous paroxysms of cough on first lying down at night. Three days before he was seen, the boy developed headache, which has persisted constantly until the present time, and he had other typhoid symptoms. A Widal test, made on the third day after admission, was negative, again negative on the ninth and fifteenth days, and finally positive on the twenty-first day of the disease. The patient ran through a rather typical, mild attack of typhoid fever without disagreeable symptoms. The heart-condition seemed but little influenced by his illness. He was seen about 3 months later with an attack of bronchopneumonia which had apparently no ill effect upon his cardiac condition. When the breath is held at the end of expiration there is a visible pulsation in the second interspace to the left of the sternum. The cardiac condition was as follows: There is a faint systolic thrill palpable over the entire pericardium, which is especially distinct along the upper edge of the sternum in the third and fourth interspaces. Auscultation reveals a rather rough, blowing, systolic murmur heard over the entire precordium, and to some extent over the entire anterior portion of the left chest, with its point of maximum intensity in the second left interspace. Over the portion of the heart extending to the right of the sternum a peculiar, loud, flap-like, systolic sound is heard, which suggests the loud first sound of mitral stenosis. There is no accentuation of the pulmonary sound. The murmur is believed to be due to obstruction at the pulmonary orifice. [J.M.S.]

5.—Vander Bogert reports the case of suppression of urine in a girl, aged 5 years, who had a history of not having passed her urine for a period of 19 hours. The trouble began 4 days before admission, with severe pain in the abdomen, which caused the patient to lie with thighs flexed. She became very constipated and her abdomen was tender to pressure. There was no history of vomiting, nor of any symptoms referable to suppression of urine. Soon after admission she passed urine. Her temperature was 101.2° F.; pulse, 120; respiration, 48; and from that time the temperature varied between 98° and 102.5°, rising in the evening and falling to normal in the morning until July 16, when it rose to 103.4°. The throat was found to be inflamed and a dose of antitoxin was given. The temperature gradually fell and on July 19 reached normal, where it practically remained until the child left the hospital on August 6. In the 2 weeks following admission the daily amount of urine never exceeded 9 ounces, and only twice did it reach that amount. On July 23 it increased suddenly to 13 ounces, and at 7 o'clock that evening a round worm, measuring 27 cm. in length was passed by the bowels. From that time until the child left the hospital, on August 6, the daily amount of urine averaged 12 ounces. Frequent chemist and microscopic examinations of the urine were made, but always with entirely negative results. Lumbricoid eggs were found in the stools on July 25 and eggs of the Tricocephalus dispar on the 29th. The patient was subsequently treated by calomel and santonin for 3 successive nights, but no more worms were passed. [J.M.S.]

2.—Symptoms of compression of the spinal cord or nerve-roots may be produced by syphilitic disease of the vertebrae such as syphilitic caries, necrosis, gumma, exostosis, periostitis, or osteitis. This is an exceedingly rare form of

spinal syphilis, and may at first be mistaken for tuberculous caries or tumor of the vertebrae. The diagnosis is based on (1) the evidence of disease of the vertebrae, with or without implication of nerve-roots and spinal cord; (2) the absence of indications of tuberculous disease, carcinoma, or tumor-growth in any part of the body; (3) the evidence of previous syphilitic infection; (4) the good results of anti-syphilitic treatment. In another very rare form there are symptoms of **chronic meningitis**, without indications of involvement of the spinal cord. The evidences of previous syphilitic infection, the absence of fever, the absence of any indication of tuberculosis or of spinal caries, are important points in the diagnosis. **Meningomyelitis** is the most common form of spinal syphilis. There are meningeal symptoms first, followed, in course of time, by symptoms of involvement of the spinal cord. The cord symptoms consist of paraparesis or paraplegia, usually with increase of the deep reflexes, and rigidity, and frequently with bladder-symptoms and sensory disturbances. There may be partial or complete anesthesia to all forms of sensation; but often some forms are affected and others spared; sometimes loss of sensation to temperature (especially to cold) is the chief or only sensory disturbance. Pathologically, both the meninges and the cord are affected. Syphilitic disease of the bloodvessels usually plays an important part in the pathologic anatomy. The nervous elements of the spinal cord are damaged (1) by cell infiltration or gummatous infiltration; (2) by softening or degeneration, following partial or complete obliteration of the bloodvessels. Sometimes the symptoms of spinal syphilis resemble those of **acute transverse myelitis**, or even of spinal hemorrhage. There is a sudden onset of paralysis of both legs, with paralysis of bladder and rectum. There may be loss of all forms of sensation, or analgesia and thermoanesthesia only; or thermoanesthesia, whilst other forms of sensation are normal. This form is known as **acute syphilitic paraplegia**. **Erb's syphilitic spinal paralysis** is still another form of the disease. In this condition the patient presents the familiar symptoms of spastic paresis or paralysis, as regards gait, attitude and movements. The patellar tendon reflexes are increased, and ankle-clonus is present, but there is relatively only slight muscular rigidity. The bladder is constantly affected. As a rule, there is only slight though constant affection of sensation. The onset of the disease is gradual, seldom rapid. In the form characterized by **paraplegia with combined degeneration in the posterior and lateral columns**, the chief symptoms during life are paralysis of both legs with rigidity, and bladder and rectal symptoms. In rare cases of spinal syphilis the symptoms have been those of a localized meningeal or intramedullary spinal tumor, and a **gumma** has been diagnosed. In addition to the clinical forms already mentioned, there are a number of other rare varieties, in which the symptoms often resemble those produced by nonspecific cord lesions: 1. Cases of Brown-Sequard's paralysis due to a unilateral lesion of the cord. 2. Cases of triplegia, in which both legs and one arm are paralyzed. 3. Cases somewhat simulating disseminated sclerosis, in the evidence of multiplicity of lesions; these are due to multiple syphilitic lesions. 4. Cases simulating lateral sclerosis; due to secondary sclerosis of the crossed pyramidal tracts of the cord, with slight changes elsewhere. 5. Cases simulating anterior poliomyelitis. 6. Cases simulating amyotrophic lateral sclerosis or progressive muscular atrophy; due to meningomyelitis in the lower cervical region. 7. Cases simulating pseudohypertrophic paralysis in the gait and manner of rising into the erect posture, but differing in the severe pain in the back and limbs, and in other symptoms. Such cases are probably due to chronic syphilitic meningitis in the lumbar and sacral regions of the cord. 8. Cases simulating syringomyelia as regards the sensory symptoms; due to meningomyelitis of special distribution. 9. Cases simulating locomotor ataxia due to a meningomyelitis invading the posterior columns of the cord, or to a gummatous infiltration of the posterior columns. The question of the syphilitic origin of true locomotor ataxia is unsettled. Pathologically, the changes in this disease are not of a syphilitic nature in the strict sense, and the disease can only be regarded as a postsyphilitic degeneration by those who attach the greatest importance to the connection between tabes and syphilis. It must be allowed that in a small proportion of cases of tabes there is no evidence or

probability of previous syphilitic infection. But there can be no doubt that a history of venereal disease, of some form, is obtained much more frequently than in the cases of other chronic affections of the nervous system. In 32 cases of spinal syphilis which have come under Williamson's observation the forms of disease were as follows: Syphilitic disease of the vertebrae, 0; chronic syphilitic meningitis, 3; meningomyelitis, 16; acute paraplegia (acute syphilitic myelitis), 6; chronic syphilitic spinal paralysis (Erb's form), 4; gumma of the cord (verified), 1; triplegia, 1; pseudotabes, 1. The pathologic changes produced by syphilis may be divided into 3 classes: 1. Those that indicate syphilis most clearly, such as gummata, or gummatous infiltration of the meninges or cord; minute gummatous nodules in the walls of the vessels; and inflammation of the meninges, followed by caseous and fibroid changes. 2. Changes that are very suggestive, but not quite conclusive, of syphilis, such as disease of the bloodvessels, endarteritis, and periarteritis, endophlebitis and periphlebitis. 3. Changes secondary to the vascular disease, such as thrombosis of spinal vessels, or complete or partial obstruction of the vessels, from thickening and disease of their walls. As a result of either of the 2 vascular changes, softening and degeneration of nerve-elements occurs; occasionally spinal hemorrhage is produced. Following the destruction of the nerve-elements, ascending and descending sclerosis gradually develop. A thorough antisiphilitic treatment should be prescribed, and there is good evidence that mercury and potassium iodid are of service. After the 2 drugs have been employed together for a time, it is best to use them alternately. [J.M.S.]

4.—Robson recites the case of an ironworker suffering from a growth on the left side of the tongue, which presented the usual characters of an epithelioma. As the growth was small and limited to the left side, half of the tongue was removed with the aid of the ecraseur. A portion of the growth was examined microscopically, with a view to confirming the diagnosis, when the following very peculiar appearances presented themselves. In addition to an ordinary epithelioma invading the substance of the tongue from the surface, between the muscular fibers, and lying in their long axes, were numerous **encysted Trichinae spirales**. The parasites showed evidence of calcification, indicating their somewhat remote advent. The specimen, besides being a pathologic curiosity, is interesting, inasmuch as the irritation caused by the calcified trichinae might prove a factor in the causation of the growth. No history of any illness, such as trichinosis, could be elicited; and a careful examination of the right half of the tongue failed to demonstrate any signs of disease. [A.B.C.]

3. A Case of Multiple Typic Periostitis. H. CONRADT.
4. The Pathology and Therapy of a Douglas Abscess in Perityphilitis. J. ROTTER.
5. The Treatment of Scabies. RICHARD SACHS.

1.—Löhlelin considers that while the difference between **ascites and ovarian cyst** is usually a distinct one, medical physicians commonly see less of the obscure cases of **peritoneal tuberculosis** than do surgeons, cases of curious tumor-formation and localized ascites being relatively frequently admitted to surgical clinics, while they are rare in the experience of medical practitioners. As distinctions in the diagnosis he particularly mentions the observation of the temperature for several days and the importance of examination under ether. He has also found that in tuberculous peritonitis there is usually some relative or absolute dulness on the left lower side of the abdomen and some resistance in that region. The explanation for this is, that with disease of the mesentery its retraction draws the bowel over to the right, while the left side is more or less completely filled with exudate. He describes a curious case in which a diagnosis of tuberculous ascites with ovarian cyst was made, but in which operation showed that there was tuberculous peritonitis with distention of the bladder and adhesions of this organ to the abdominal wall, the distended bladder simu-

lating a cyst. He insists upon the importance of rectal examination of Douglas's pouch. One frequently feels large tubercles in this way, but the small tubercles are even more common and can be readily felt. One can also by rectal palpation determine the degree of improvement after operation by noting the condition of the tubercles. Another point which he recommends is an incision in the posterior vaginal vault and examination of the local peritoneum in this way, and, if necessary, excision of small bits of diseased serous membrane. [D.L.E.]

2.—The case reported was that of a man of 41 who had apparently a croupous pneumonia. Ten days later he was admitted with a severe bronchitis, some fever, albuminuria, and marked delirium. Four days afterward small **hemorrhages** appeared on the left arm which increased in size and in number, and were markedly elevated above the skin surface. The **purpura** persisted, new hemorrhages appearing practically every day and involving all portions of the body. At one time there was free hemorrhage from the folds of the skin, and some hemorrhage from the mucous membrane. There was marked symmetry in the hemorrhage. The most peculiar and important fact noted was that there were also, in all, 17 more or less deep hematomas formed, and that they were always upon the left side of the body. Bacteriologic examination of the blood was negative, there was no involvement of the heart, and the spleen was not enlarged. Unusual conditions noted were severe sweats, and a remarkably quick coagulation of the blood. The latter was so marked that it was almost impossible to get blood for counting and hemoglobin estimation, the flow stopping so quickly. The case was believed to have demonstrated that nervous influence acting upon the vasomotors was responsible for the hemorrhage. This conclusion was due to the limitation of the hematomas to the left side, a condition which could not have been caused by a general dyscrasia of the blood, but must have been due to some local cause. The blood-examination showed a normal number of red and white cells, with slight reduction of the hemoglobin. An interesting observation was the fact that the blood plates were much increased in number. This is chiefly of interest in relation to the fact that there is evidence that the blood platelets are of importance in blood coagulation, and that they increase in those conditions where the blood tends to coagulate with undue rapidity and decrease in the contrary conditions. [D.L.E.]

3.—The case occurred in the person of a girl of 15. She had an attack of typhoid fever in January; 6 months later she had **periostitis** of the tibia, skull, and left hand. Operation showed pus, and the presence of the typhoid bacillus. An interesting fact was the observation that while this bacillus gave reaction in high dilution with the blood of a rabbit inoculated with typical typhoid bacilli, the patient's blood would not react with typical typhoid bacilli or with the bacilli isolated from the pus even in a dilution of 1 to 30. The bacilli were virulent to guineapigs. The explanation of the negative result of the agglutination test may be found in the fact that the agglutinating power of the blood is often soon lost after general typhoidal infection, and there was no general infection with typhoid from the abscesses. The observation is of importance in showing that post-typhoidal metastatic infection need not necessarily give a Widal reaction. In other words, that a negative result with a Widal test is not an absolute sign of the absence of local typhoidal infection. These cases Conradt considers to be not the result of a specific tendency of certain tissues to infection with typhoid while other organs have become immune. He thinks they are rather the result of modification of the bacilli themselves; they have become less virulent, and while they live in the body they have lost their infectiousness. Some local conditions, such as trauma, then reduces the resistance of the tissues and the bacilli again assume a relative virulence. He thinks that the typhoid bacilli cause local suppuration only when they have lost their specific character. [D.L.E.]

5.—The treatment recommended is the use of **peruol**, which is a benzylester of benzoic acid. This is mixed with oil in proportion of 1 to 3, energetically rubbed in all over the body, with the exception of the head and neck. This is twice repeated within 36 hours, then a bath is given, and the clothes are changed. Thirty-five cases so treated all improved very quickly, and in only 4 was a recurrence noted; in these cases the treatment was not properly carried out,

the clothes were not changed, so there was opportunity for new infection. Peruol was found to kill the parasites in experiments more quickly than any of the other substances ordinarily used for scabies. The author has also used **Shorwell's method** with satisfactory results in 25 cases. There is likely, however, to be more irritation of the skin, and it should not be used when the skin is delicate or particularly in children. Peruol causes no irritation of the skin or other organs, has no odor, and does not stain the clothes. [D.L.E.]

4. The Pathology and Therapy of Bladder Tuberculosis. LEOPOLD CASPER.
5. The Etiologic Significance of Trauma. DIRSKA.

1.—Richl describes the method which he has used for obtaining viscin from the *Viscum album* (the white mistletoe), a plant very common in Europe. The product is extremely adhesive and furnishes a good basis for plasters, traumaticin and gelatin preparations. It is much cheaper than india-rubber preparations. [D.L.E.]

4.—Casper has written an article on pathology and treatment of **tuberculosis of the bladder**, basing his considerations on the study of 35 cases. In most all the cases there was tuberculous process going on in other organs. Most frequently the original foci of disease were found in the kidney, next in the genitalia (prostate seminal vesicles and testicles) and with these conditions there was generally associated more or less disease of the lung. Primary tuberculosis of the bladder was found only in 3 cases, 2 of which developed as sequels to gonorrheal cystitis. Gonorrhea plays a very important part in the etiology of tuberculous cystitis, having been present in 83% of the cases. [G.B.W.]

4. The Pathology and Therapy of Tuberculosis of the Bladder. LEOPOLD CASPER.
5. Hemianopsia and its Local Diagnostic Utilization. H. SOLOMONSOHN.

1.—Döderlein says that it has been proved by numerous researches, that it is impossible to completely **disinfect the hands**, and that in all operating the surgeon never does have an absolutely sterile wound; however, many wounds heal without inflammatory reaction, even in the presence of various microorganisms. He endeavors in his article to show that though our hopes, so far as obtaining an ideal disinfection of the hands is concerned, have been destroyed, much is to be accomplished by further research in a somewhat different direction. The question as regarding the use of gloves is a very important one and many others still unsolved await further enlightenment from some worthy researcher. [G.B.W.]

2.—The case was that of a boy who in September, 1898, fell and received a wound on the forehead parallel to and above the left eyebrow. This healed without trouble, but a few days later it was noticed that the boy, who was then 6 years old, and who had previously been entirely normal mentally, paid no attention to any words addressed to him, had a wholly expressionless appearance, and began to have severe **epileptic attacks** which were frequently repeated. He ceased entirely to speak, either spontaneously or when addressed. His physical condition seemed entirely good, but his mental condition was grievous. He made constant purposeless movements, was exceedingly dirty in all his habits, and had an abnormal appetite. He passed through an attack of measles, and was somewhat improved at first, but soon after was in the same condition as previously. He was **operated on**. The wound was found to be free from adhesions to the skull, the skull was normal, and although the dura was opened and the brain tissue was punctured, nothing

abnormal was found. The wound was therefore closed; the patient seemed perhaps slightly better after the operation, but there was little change, and he had typical epileptic attacks. The operation was undertaken in January, and the child was discharged with the advice that he should be placed in a school for weak-minded children. In the following summer the mother reported that the last epileptic attack had occurred in April, and the child at the time of the report was seemingly entirely well. He recognized all his surroundings, he was of normal intelligence for a boy of his age, epileptic attacks did not occur, and there was nothing in his mental or physical condition to indicate that he had any remnants of his previous epilepsy. The explanation for this cessation of the attacks is not readily given. Rose suggests that since the trephine opening had remained patulous this may have acted as a safety-valve regulating internal pressure. [D.L.E.]

3.—The apparatus described is one which allows of the application of a urinal to children while undertaking metabolism experiments, and while not binding the children so tightly as to make them uncomfortable prevents loss of urine. It consists of a somewhat hammock-like arrangement with pockets in the lower ends in which the legs are fastened. [D.L.E.]

4.—Regarding the diagnosis of tuberculosis of the bladder, it is noteworthy that in certain instances, the smegma bacillus has retained the carbolfuchsin stain with remarkable tenacity, resembling in this way very closely the tubercle bacillus. The 2, however, can be readily differentiated by cultivation on blood-serum and glycerin agar. The smegma bacillus develops within 24 hours and that of tuberculosis not until 10 to 14 days have elapsed. When the tuberculous process is primary in the bladder, the posterior wall is generally affected. When it is an ascending infection following disease of the genitalia, the fundus and the region of the sphincter are the parts attacked, and when the condition of the bladder is secondary to disease of the kidney or ureters, the ulceration is found around the openings of the ureters. Cystoscopy of the bladder should not be practised except in cases where diagnosis cannot be otherwise determined. As to the treatment of tuberculosis of the bladder: there is the general—consisting of proper and hygienic administration of internal medicine—the local and the operative. Regarding internal medication, Casper believes in the use of creasote and guaiacol carbonate. In the local treatment, one should never, as in ordinary cystitis, distend the bladder with irrigations. In many cases, it is probably best to inject a small quantity of fluid, the best of which is 1 to 10,000 to 1 to 5,000 solution of corrosive sublimate. Topical applications may also be made with cotton twisted on the end of an applicator. It is seldom that any toxic symptoms will be noticed from the use of the sublimate. If after 3 or 4 applications no results are obtained, little can be expected from the use of the sublimate, because the benefit of this drug is generally observed even after its first injection. The first improvement is noticed in the relief of the pain, the tenesmus being more difficult to relieve. Operations in tuberculosis of the bladder should be done only in those cases in which the tuberculous process is known to be limited to a circumscribed area. [G.B.W.]

5.—Solomonsohn has written a very specialized article on hemianopsia, going over the question in quite a detailed manner. [G.B.W.]

October 25, 1900. [26. Jahrg., No. 43.]

1. Salkowski's Determination of the Alkalinity of the Blood. WALDVOGEL.
2. Gonorrheal Nerve Diseases. A. EULENBURG.
3. Experience in Copper Factories. L. LEWIN.
4. Hemianopsia and its Local Diagnostic Utilization. H. SOLOMONSOHN.

1.—Waldvogel has found that in doing Salkowski's method for the determination of the alkalinity of the blood that when one places a given quantity (10 cc.) of sulfuric acid solution in the Schlösing apparatus over the ammonium sulfate solution and leaves it there for several days some of the sulfuric acid has disappeared. This he attributes to a physical process in which the ammonium sulfate abstracts water from the sulfuric acid solution. He uses normal sulfuric acid instead of $\frac{1}{2}$ normal as Salkowski recom-

mends, since he has found the latter to be insufficient. He therefore determines exactly the amount of fluid remaining in the sulfuric acid chamber before he determines by titration with $\frac{1}{2}$ normal NaOH how much the acidity has been reduced. He found the normal for men to vary between 350 and 400 mg., for women between 300 and 350. The effect of fever was to reduce the alkalinity, but there was no direct parallelism between the temperature and the reduction of the alkalinity, and the reduction of the alkalinity persisted in some cases when the temperature had receded to normal. In cases of slight fever the alkalinity was not always diminished. Anemias reduced the alkalinity. In one case of severe pernicious anemia associated with typhoid fever and with marked rise of temperature, he found his lowest result, i. e., 40 mg. After 60 hours abstinence from food he found in one man a reduction to 214 mg. This patient showed at this time a slight acetonuria. Waldvogel believes that after 5 days' action of the ammonium sulfate it is quite possible that some of the alkaline elements of the blood-corpuscles may diffuse into the fluid and thus cause error. [D.L.E.]

2.—Eulenburg describes the following gonorrheal complications of the nervous system: Neuralgia-form affections, muscular atrophy and atrophic paralysis, neuritis, and myelitis. Under the heading of neuralgia he places 14 cases which he has observed, including the instances of neuritis, since they cannot be distinctly separated. There were 4 cases of muscular atrophy and atrophic paralysis, and 1 of myelitis. Of the cases of neuralgia 6 affected the sciatic nerve, 2 the tibia; one of them appeared in the form of achilodynia, and another case was a neuralgia of the nerves of the arm. An important point in the cases of neuralgia of the sciatic was that the nerves of the sacral plexus were not alone affected. In 5 the nerves coming from the lumbar plexus were also affected and in 2 cases the brachial nerves. This spreading of the neuralgia to other nerves he considers an important diagnostic point. In presenting his statistics in general he has left out cases in women which were probably due to this cause since it was so difficult to demonstrate the existence of gonorrhea. In 6 cases limited to the main trunk of the sciatic, 2 were left-sided, 1 right sided, 3 on both sides, one side always being affected chiefly. In 2 cases there was reason to suppose the beginning of a tabes because of these bilateral neuralgia-forms pains. The onset of the neuralgia was from 2 months to several years after the attack of gonorrhea, but the gonococcus could still be demonstrated in most cases, or had been demonstrated shortly before the onset of the attack. The cases of muscular atrophy with atrophic paralysis were chiefly instances of atrophy about joints which had shown gonorrheal involvement. As an example he describes a case in which there had been involvement of the right shoulder, and subsequently there was atrophy of the pectorals, serratus, latissimus, and other muscles on the right side, and subsequently an atrophy of the corresponding muscles on the other side, so that the case presented a strong resemblance to progressive juvenile dystrophy. The patient improved, and ultimately became almost entirely well. As an example of cases of myelitis he reports one observed by him in which there was absence of patellar reflexes, pains along the spine of very severe degree, loss of power in the legs and in the muscles of the back, with atrophy of the muscles of the right arm and also of the legs and feet. There was some involvement of the bladder and rectum. This man recovered entire health. In the diagnosis of those conditions he insists strongly upon the importance of the discovery of gonococci in the secretion from the urethra, or the presence of chronic urethritis and its results, such as prostatitis and cystitis, or metastatic gonorrheal affections such as joint involvement, endocarditis, diseases of the endometrium and adnexa. Certain peculiarities in the symptomatology of the affections themselves are important. First, a tendency to appear in the form of sciatica with coincident involvement of the lumbar and sacral nerves, and particularly of the genital nerves; also a tendency to the occurrence in young persons to sudden severe paroxysms of pain often accompanied by intermittent fever, also a tendency to be associated with sexual neurasthenia. Muscular atrophy or atrophic paralysis is likely to be situated about joints commonly affected with gonorrhea, it follows certain forms of arthritis, and is likely to involve the corresponding muscles on the other side of the body. The gonorrheal affections of the cord have a ten-

ency to some resemblance to degeneration of the posterior columns, but are distinguished by a coincident tendency to involvement of the motor sphere (*i. e.*, muscular atrophy), absence of pupillary symptoms and by the general course. The prognosis is not unfavorable. Treatment should be instituted according to the individual case, but Eulenburg has found iodipin, particularly when given subcutaneously, to be valuable. [D.L.E.]

3.—Lewin reviews the past work on copper poisoning, and reports the results of his own observation of a large series of cases and the influence upon himself of the inhalation of copper in factories. He decides that there is every evidence that large amounts of copper, when taken in through the mouth or through the lungs, if in soluble form, are likely to cause acute poisoning, the symptoms being due to the direct effect of the copper upon the albuminous tissues and the formation of copper albuminate. Symptoms which are due to absorption are extremely rare. Copper dust when inhaled may cause acute disturbance of the gastrointestinal tract, sialorrhea, and similar disturbances, which soon disappear. If the influence is chiefly upon the respiratory tract it causes an uncomfortable feeling of irritation in the larynx, a feeling of pressure under the sternum, sometimes a little spasm of the glottis, cough, and expectoration. All these symptoms are those of any mechanical irritant and are such as are caused by any metallic salt. He does not think that there is any evidence that any specific or important poisoning with copper is seen in workers in copper. The affections to which these people are subject are due, he thinks, to the unhygienic influences under which they live, or to their poor nourishment, and similar conditions. [D.L.E.]

4.—Solomonsohn concludes his article on hemianopsia by reporting in detail 3 cases. [O.B.W.]

Wiener klinische Wochenschrift.

September 20, 1900. [13. Jahrg., No. 38.]

1. The Etiology of Primary Acute Gastrointestinal Diseases of Infants. THEODOR ESCHERICH.
2. Investigations Concerning Tonsillotomy and its Possible Relation to the Diphtheria Bacillus. L. HARMER.
3. A Contribution to our Knowledge of Scarlet Fever and Measles. JAROSLAV ELGART.

1.—Escherich classifies the **gastrointestinal diseases of infants** as follows: A. Exogenous intoxications (produced by the ingestion of spoiled milk containing toxic substances). (a) Toxic catarrh of the stomach or intestine. (b) Cholera infantum. B. Chymus infection (endogenous intoxication from abnormal decomposition of the intestinal contents and secondary inflation of the intestinal wall). (a) Bacterial dyspepsia (acid diarrhea). (b) Dyspeptic catarrh. C. Intestinal infections (inflammatory irritation or invasion of the intestinal wall by pathogenic bacteria). (a) Inflammatory catarrh (inflammatory diarrhea). (b) Inflammation: gastritis, gastroenteritis, enteritis, enterocolitis, colitis. Escherich also postulates a number of theses, the more important of which are: 1. That the bacterial flora in the infant's intestine, although derived from without, is constant and autochthonous owing to the constant chemico composition of the food and intestinal contents. 2. The flora of the stool under normal conditions is within wide limits independent of the bacteria introduced with the food. [D.R.]

2.—Harmer's studies led him to the conclusion that after every **tonsillotomy** a deposit develops in the wound within 24 hours; sometimes a distinct membrane is produced. The deposit consists principally of fibrin, leukocytes, and necrotic parts of the wound surface. Bacteria, principally cocci, are present in the deposit, and probably play an etiologic role. The diphtheria bacillus is not the cause of the deposit, but a bacillus belonging to the pseudodiphtheria bacillus group is often present. Danger does usually not attend the tonsillotomy deposit, but it is well to apprise the patient in advance. During the existence of the diphtheria epidemic it is not wise to perform laparotomy, at least not without the necessary precautions. [D.R.]

3.—Elgart is of the opinion that in **scarlet fever** and **measles** the exanthem is not the essential element, and that the primary disease is in the throat and the nose-conjunctiva respectively. On the strength of this view he endeavored to

prevent the spread of endemics by applying antiseptics to the mucous membranes. He caused children to inhale various solutions—lime-water, boric acid, in 3% solution; iodine trichlorate, in 0.05% solution; sodium chlorate, in 3% solution. The effect was that no case of either measles or scarlet fever occurred afterwards in the hospital. Scarlet fever having been introduced, all cases remaining (19) and those afterwards received (98) were treated in the way designated, and none developed scarlet fever. The author therefore concludes that the **inhalation of disinfecting solutions** is capable of preventing the development of measles and scarlet fever endemics, provided the intensity of the original case and the type of the prevailing epidemic is mild. [D.R.]

Centralblatt für Gynäkologie.

October 6, 1900. [No. 40.]

1. Cystic Growths in Ovarian Remnants. I. E. WALDSTEIN.
2. Abortion in Consequence of Gonorrhea of the Uterus. DRAGHIESCU and SION-MOSCHANA.

1.—Waldstein reports 4 cases of **cysts** occurring in some remnants of ovarian tissue which has not been removed in the radical operation, because of existing adhesions and decomposing tissues which it was necessary to take away piecemeal. The growths were all successfully removed and the patients recovered. [W.K.]

2.—Draghiescu and Sion-Moschuna believe that more researches should be made in regard to the deleterious influence of the **gonococcus** on the **gravid uterus**. They report a case where abortion occurred, after every effort was made to stop it, and the bacteriologic examination developed the fact that the diseased lining membrane of the uterus showed groups of diplococci identical with the gonococcus of Neisser, together with staphylococci and the ordinary bacteria found by Döderlein in normal vaginal secretions. [W.K.]

October 13, 1900. [No. 41.]

1. Upon Pathology of the Placenta. EDMUND HERRMANN.
2. A Case of Atrophy Caused by Ligating the Vessels in an Apparently Tuberculous Bilateral Salpingitis, on Account of the Impossibility of Extirpation. A. C. LINDFORS.

1.—Incited by the work of Bulius, who demonstrated a moderate proliferation of **syncytium** in the **placenta** of an eclamptic patient, Herrmann made an examination of the placenta of a nephritic woman, and found in the placenta of 8 months and of a full-term placenta, on the one side persistence of syncytium in a condition such as is usually seen only in a 4 to 6 months placenta, and on the other side the appearance of the seat of the syncytic proliferation. [W.K.]

2.—Lindfors reports a case of a woman, aged 20, upon whom he operated for bilateral subacute **salpingoophoritis**. He found both tubes much enlarged, the surface being thickly covered with innumerable tuberculous nodules of red-gray color; and they were so imbedded by firm adhesions with ovaries, intestines, etc., that he considered extirpation impracticable; and instead, according to the principles of Antal, placed ligatures of silk en masse on the uterine end of the tube and the infundibulopelvic ligament on both sides, thus producing atrophy of the tubes. The patient recovered, and examination 2 years after the operation showed her in an apparently healthy condition with very small ovaries and string-like remnants of the tubes. It is indeed rare that removal of the adnexa is prevented by adhesions, but when these or other complications prevent their removal, it is well to know that ligating the vessels properly will produce atrophy and check the progress of the disease as in the case reported. [W.K.]

October 20, 1900. [No. 42.]

1. The Disinfection of the Obstetrician's Hands. R. KOSSMANN.
2. Correction of Ahlfeld's Article, "Some Remarks on the Tübinger Experiments in Disinfection of the Hands." (*Centralh. f. Gynäkologie*, 1900, No. 37.) TH. PAUL and O. SARWEY.

3. Remarks upon Ahlfeld's Article, "A Contribution on the Question of the Genesis of Puerperal Fever." von KRONIG.

1.—Kossmann in discussing the vexed question of **disinfection** of the hands recommends a three-fold procedure: Three minutes cleansing with Marmor's soap, first without and then with water; then 7 minutes washing in 20% solution of chinosol, and after drying immerse them in chiroi, let them dry, 3 minutes. [W.K.]

2.—Paul and Sarwey say that their experiments show with certainty that the hands cannot be made free from germs by means of hot water and alcohol disinfection as recommended by some writers. [W.K.]

3.—Kronig corrects some of Ahlfeld's misunderstanding and declares that, in our ignorance of the biologic peculiarities of the infectious puerperal bacteria, Ahlfeld's assertion that 96% alcohol solution used as a disinfecting agent destroys all kinds of bacteria germs on the person or hands of the obstetrician, cannot be accepted without question and further examination. [W.K.]

October 27, 1900. [24. Jahrg., No. 43.]

1. Something upon Forceps as an Instrument for Improving Fetal Presentation in Reply to Dr. Modest Popescul, "Face Presentation; Chin Posterior." I O SCHAEFFER.
2. A Case of Fatal Hemorrhage from a Ligated Umbilical Cord. J. BALIN.

1.—Schaeffer's conclusion based upon experience is that in **unfavorable face and brow presentation**, if the birth-passages are normal, the **use of forceps** to correct the presentation or to extract the child is **usually contraindicated**. If the head is small, with short occiput, or if is freely movable in relation to the body, the use of the hand guided by sufficient experience may save the life of an otherwise lost child. The attempt to use forceps is, however, forbidden. For a firmly fixed head the change of presentation manually according to Rose or Valland is first to be tried, and this will help to make clear the difficulty in each case. Also for the anterior frontal presentation with sinking of the brow, with normal birth-passages, with large head and long occiput, great caution must be observed in bettering the position. In conclusion, it must be observed that lever forceps are liable to cause the long enduring reflex nervous disturbances incident to excessive distention and bruising of the parts. [W.K.]

2.—Balin reports a case of **fatal hemorrhage from a ligated umbilical cord**, and after discussing the causes thereof concludes with words of Runge: "A hemorrhage before the fall of the navel cord can only take place when the umbilical cord has been carelessly tied. In order to make such hemorrhage impossible we must demand a most definite carefully executed ligature of the umbilical cord." [W.K.]

Centralblatt für innere Medicin.

October 20, 1900. [24. Jahrg., No. 42.]

1. A Contribution to the Pathological Action of Alcohol. GEORG ROSENFELD.

1.—A review of the previous work upon the **influence of alcohol upon the liver** is given, and Rosenfeld then gives his own investigations, which consisted in the administration of definite amounts of alcohol to dogs which had been kept without food for 6 or 7 days. The alcohol was administered through a stomach-tube in quantities of $3\frac{1}{2}$ to 4 cc. of 96% alcohol, given once or twice daily in large amounts of water. The animals were usually made decidedly drunk, but after as long as possible a period of poisoning they were killed before spontaneous death occurred. The livers were then removed, and the glycogen and the fat estimated by the methods of Külz and with Soxhlet's extraction respectively. The chief results of the investigation were that if doses of $3\frac{1}{2}$ to 4 cc. of alcohol per kilo of body weight were given as many as 4 times a day to starving animals, the liver was found to contain as much as 22% of fat—more than double the normal. The livers of such animals were found to be extremely poor in glycogen. The use of cane sugar with the alcohol decreased the amount of fat in the liver. When con-

trasted with the amount of alcohol which men take it may readily be seen that as much as 4 cc. per kilo of body weight is often taken by men in the form of the heavier liquors, and that even two liters of Pilsener beer will contain as much as 1 cc. of alcohol per kilo of body weight. This demonstrates that it is entirely possible for alcohol to produce fatty liver and to decrease the glycogen of the liver. The use of alcohol over a period of days, with subsequent stoppage of the dosage, was followed by recovery. This is analogous to the fact often observed that a few large indulgences in alcohol do less damage than continuous tipping. The lessened effect of the alcohol when sugar was given is analogous also to the fact that in man, if the alcohol is taken with food it is borne better than when taken on an empty stomach; but the animals which were given the alcohol alone nevertheless lived longer than those that were given sugar with the alcohol, and it shows that one who eats when he takes alcohol is by no means secure from disease due to the alcohol. [D.L.E.]

Neurologisches Centralblatt.

October 15, 1900. [No. 20.]

1. Inequality of the Pupils Resulting from the Different Action of Direct and Indirect Illumination. A. PICK.
2. The Pathogenesis of Epilepsy. Z. BYCHOWSKI.
3. Is it Permissible to Regard a Degeneration in the Posterior Columns that Diminishes in the Lower Part of the Cord, without Further Consideration, as One Proceeding from Above, Downward? (Acute Myelitis of the Spinal Cord After Amputation) BIKELES.
4. The Tone Conduction of the Bones of the Skull in Diseases of the Brain and Its Membranes. F. WANNER and H. GUDDEN.
5. The Clinical Position of the So-called Erythrophobia. A. FRIEDLÄNDER.

1.—It is generally believed by ophthalmologists that often when the pupils are illuminated by lights of different intensity they are approximately equal excepting in very sensitive individuals. Pick, however, has observed that in many cases of epilepsy, neurasthenia, and other forms of functional psychosis, the **pupils may vary considerably** if the patient stands with a side toward the source of illumination, as for example, a window. Under these circumstances the pupil receiving the most light is always narrower. This seems to be due to a hyperesthesia of the centripetal apparatus. [J.S.]

2.—The patient, a man of 28, had his first attack at the age of 26; the second occurred 8 months later; the third at the end of the first year. Subsequently the attacks occurred at somewhat briefer intervals, lasting longer, and being more severe. These attacks were preceded by dizziness, and a sense of darkness; the patient then became unconscious and fell to the ground. There were no convulsive movements, but subsequently the patient felt exhausted. Aside from chronic constipation there is no other disease. For 12 or 13 years he has been engaged in preparing tobacco for the market, treating the leaves by a secret process, and for this reason working in a small room that was absolutely without ventilation. Every day he stood from 6 to 8 hours in an atmosphere loaded with the fumes of the leaves. Bychowski therefore ordered him to work in a larger room and to expose himself as little as possible to the nicotine-laden atmosphere. The result proved the correctness of his belief that **nicotin poison** was the cause of the attacks, the patient recovering completely. It therefore seems to be fairly well established that in this case the **epilepsy was due to chronic tobacco poisoning**. [J.S.]

3.—Bikeles, after calling attention to the article published by him in February of the present year, in this *Centralblatt*, reports two other cases, one of **acute myelitis**, in which the changes were identical with those previously described, and one of a spinal cord obtained from an individual dying 15 years after amputation of the left thigh. The **changes in the spinal cord** were very curious; in the lumbar region there was no appreciable difference in the posterior roots, there was, however, a distinct diminution in the size of the anterior and posterior cornua of the gray substance. There was also slight diminution in the size of the right posterior column at the level of the first and second lumbar segments,

which became more pronounced in the dorsal region. In the upper portion of the dorsal region there was a slight area of paleness in the neighborhood of the posterior median septum, and, in the cervical region, Goll's column was distinctly degenerated. Bikes concludes from this that in the lower portions of the cord the degeneration was masked, by the fact that the fibers were uniformly distributed throughout the posterior column, whereas in the upper portion the long fibers were grouped together and, therefore, gave rise to a distinct degenerated area. The long fibers passing out through the posterior horns, apparently do not degenerate. [J.S.]

4.—The authors continue their article giving the results of the examination of various cases of chronic alcoholism, epilepsy, meningitis, idiocy, progressive paralysis, and infantile cerebral paralysis.

5.—Friedländer continues his description of cases of **erythrophobia**, concluding with 5 observed by himself. The first of these, a man of 30, had a distinctly neuropathic ancestry, and he had often suffered from migraine. At the age of 10 he blushed when spoken to by a young woman, and subsequently every time he saw this person. Later the blushing occurred whenever he was spoken to in the street. He had difficulty in sleeping unless he had prayed for all his relations, and had also various imperative movements; he also suffers from dermatographia; nevertheless he is an accomplished orator. The second occurred in a woman of 30, with marked neuropathic ancestry. The symptoms disappeared at the age of 18, but she is still excessively emotional. The third case, an artist of 33, also with neuropathic ancestry. He has various imperative movements and conceptions. The fourth case was a woman with neuropathic ancestry, imperative conceptions and suicidal tendencies. She is, nevertheless, capable of managing her household acceptably. The fifth case was a physician, 30 years of age, whose mother had various neurotic tendencies. He first noticed the tendency to blush at the age of 30; he became readily irritated, had tachycardia, and the symptoms gradually increased so that the mere naming of a person whom he knew caused the blushing. These symptoms had continued with varied intensity until Friedländer employed hypnosis, when, as a result of suggestion, they disappeared completely. It follows from this case, and from those detailed in the literature, that erythrophobia is not a disease, but simply a neurotic manifestation in a person suffering neuropathic heredity. Under these circumstances it hardly seems necessary to continue the name, except possibly for the purpose of describing the symptoms. [J.S.]

5. On Reform in the Dressings of Military Surgery. JULIUS PORT.
6. Hemorrhage Following Compression of the Trunk. HEINRICH BRAUN.
7. A Shoe Adapted for Walking on the Toes. EDM. ROSE.

1.—Goebell reports 2 cases of **reducible interstitial inguinal hernia** which had been cured by radical operation at the Kiel clinic during the past winter. The first case was a man of 49, who had an undescended testicle on the left side and had had for the past 10 years a reducible inguinal hernia on the left side which had never given any trouble until 6 weeks before his admission into the hospital. On examination an hourglass-shaped tumor was found, half lying above the external ring and the other half in the scrotum. After reducing the scrotal part of the hernia, it was found possible to reduce only about half of the interstitial portion because it was pushed down into the scrotum. If, however, the finger was placed on the external ring, after the scrotal hernia had been reduced, the reduction of the interstitial portion was easily done. After the reduction had been done, a slit could be felt in the subcutaneous tissues, extending outward from the external ring, which would admit 3 fingers,

and when the patient coughed the finger readily perceived the impulse of the intestines against them. At the operation the hernial sac was found to consist of 2 parts, one occupying the scrotum and the other, about 5 cm. in length, lying between the external and internal oblique muscles. The sac was dissected free and removed and the operation completed after the manner of Bassini. The atrophied testicle was found 2 or 3 cm. above the bottom of the scrotal sac. The second case was a man of 50 who had had a right-sided inguinal hernia since 14 years of age, and which for the past 14 years had extended upward until about 2 years previous it had reached the lower edge of the ribs. The testicle on the right had not descended into the scrotum, though the patient had noticed it several times at the external ring. The hernia was reducible, the whole mass going back into the abdomen with a gurgling noise. After the reduction, by invaginating the scrotum 2 fingers could readily be pushed through the external ring and it was also noticed that if the fingers were carried in a more external direction, an opening could be felt which would admit 3 fingers. At the operation an incision was made from the anterior superior spine of the ilium to the external ring, 22 cm. in length. The whole sac was dissected free from the scrotum and from between the external oblique and internal oblique muscles. The testicle was found in the interstitial part and together with the spermatic cord and the hernial sac was removed. The excess of tissue was cut away and the different layers of the abdominal wall carefully sutured together. Goebell concludes his paper by a rather extensive review of the literature and classifies and describes the different varieties of interparietal inguinal hernia. [G.B.W.]

2.—Fertig reports a case of **torsion of the intestine** due to a cyst of the mesentery, in which death followed after extirpation of the cyst from gangrene of the intestinal wall. The patient was a man of 30, who began to have severe cramp like pains about 4 months before his admission to the hospital. These pains were particularly severe after eating. A month later, he noticed for the first time a tumor in the abdomen, situated near the umbilicus, and about the size of a man's fist. Though he was somewhat constipated and for the past 3 weeks has had no fecal movement, his abdomen was not distended. On opening the abdomen, a cyst round in shape, and about the size of a man's fist, was found situated in the mesentery. Resection of the adjoining part of the intestine and removal of the cyst were done, and the abdomen closed. Two days after, the patient died, apparently from peritonitis. At the postmortem a portion of the intestine, near the seat of the operation, was found twisted twice on its long axis, and the supplying artery was closed by the twist. A larger part of the small intestine was found to be gangrenous. A detailed study of the postmortem findings showed that the torsion must have originated sometime before the operation, probably a quarter of a year previously, and in all likelihood was originally due to the presence of the cyst. No other morbid conditions could be found to account for the twisting. [G.B.W.]

3.—Hirschkopf reports the results of 191 patients, presenting 236 **hernias**, operated upon by Kocher or his assistants. First, as regarding the radical operation in infants, Hirschkopf says that the only real danger in children is one of infection, but this can be avoided by the proper observance of aseptic technique, and the use of occlusive bandage. There is, therefore, no reason why children should not be operated upon as soon as the hernia is discovered. As to results obtained by Kocher, infection occurred in 5.7%, and out of 191 patients there were no mortalities. Regarding the relapses in those cases that were operated upon by his invaginating method, in 83 cases 1.2% showed a return of the hernia. In the older method practised by Kocher of simply displacing the hernial sac, there were relapses in 3.6%. The method of invaginating the hernial sac is briefly as follows: After the sac has been dissected free of the surrounding tissues, a small opening $\frac{1}{2}$ cm. long is made 1 to 2 cm. outside of the internal inguinal ring. By blunt dissection the peritoneum is reached and opened. Through this opening a pair of long forceps is passed into the abdominal cavity to the hernial sac. The forceps is carried through into the sac to its extremity, on which it is closed, and by withdrawing the forceps the hernial sac is invaginated through its entire length and drawn partially out of the small lateral wound. Regarding the advantages of the Bassini operation and that of

Kocher, statistics gathered from outside sources give the following percentages: Mortality after the Bassini method is 0.3% to 0.5%, and after Kocher it is zero. Relapses after Bassini occurred in 4.4% cases and after Kocher's invaginating method, 1.2%. [O.B.W.]

4.—Fischer has written an elaborate article on **purulent osteomyelitis of the cranium** following injury. He says unless the skull is fractured, it is very seldom that an extradural hemorrhage is caused by traumatism. On the other hand, it is very rare for fracture of the internal table of the skull to occur, without an extradural hematoma being formed. It is not necessary when the trauma has laid bare the bone of the skull that suppuration and necrosis should take place. In fact, more often the periosteum either reunites or the bone becomes covered by a layer of granulating tissue. If the wound has traversed the aponeurosis of the occipito-frontalis, there is apt to be an extensive suppuration with destructive process resulting, because the aponeurosis offers a firm barrier to the exit and release of the suppurative processes. When pus is formed under the aponeurosis, it very frequently involves the muscles, which breaking down cause thrombosis of veins communicating with the dura. The term "bone contusion" should be only used in those cases in which the periosteum has become loosened from the bone. This may occur in an open wound or through the action of a subperiosteal hematoma. Hospital gangrene, of course, when it occurs, is a most serious complication. When the soft parts have been destroyed for any extent, necrosis of the bone generally takes place. Uncomplicated fractures of the internal table, of course, do not cause either otitis or purulent pachymeningitis. Traumatic purulent otitis of the skull, with great loss of substance, is a comparatively rare occurrence. [G.B.W.]

5.—Port reviews in a rather detailed manner the history of **military surgical appliances** from the beginning of the nineteenth century up to the present time. He says that the treatment of the wounded on the field has not kept in line with the advance of civil surgery, especially regarding mechanical apparatus for the treatment of wounds involving the bony structures. He describes various appliances made out of strip iron, suitable for all the more important of the injuries likely to be met with. They include skeleton splints for the aseptic and septic bullet wounds fracturing the bones of the lower leg, an apparatus for treating wounds of the rump and upper portion of the thigh, appliances for the treatment of bullet fractures of the shoulder, upper arm and elbow, for both septic and aseptic wounds, a splint for suppurating bullet fractures of the lower arm and ambulatory apparatus. [O.B.W.]

6.—Braun reports an interesting case in which a man was caught between machinery, so that his body was severely **compressed**. **Marked hemorrhages** occurred all over the head and neck; the eyelids became swollen, so that the eyes could not be seen; the entire face and upper part of the neck were distended and of a blue-black color; and small extravasations of blood, not disappearing on pressure, dotted the whole surface. The patient was absolutely blind, even after the lids were opened. Death occurred 30 hours after the injury. At the postmortem, the orbital fat was found infiltrated with blood. The mucous membrane of the nose was dotted with minute hemorrhages, and the intramuscular tissues of the neck were stained a dark red with infiltrated blood. The larger part of the tissues of the head and neck were markedly congested, or contained extravasated blood, though no signs of hemorrhages could be found in the brain or medulla. More or less dark red fluid was found in the pleural cavity, and several ribs were found fractured. In the abdominal cavity considerable fluid blood was found. Microscopic examination of part of the congested skin showed the capillaries and small veins to be markedly filled with blood-cells. The arteries were empty, and there were numerous small hemorrhages most plainly seen in the cutis. [O.B.W.]

15.—Danegger has performed a series of experiments, and made a number of clinical investigations regarding the use of **ligno sulfite** as a cure for pulmonary tuberculosis. This was originally discovered by accident; some phthisical workmen compelled to spend a considerable amount of time in rooms where wood-fiber was being digested, found that they experienced great relief. The material is usually prepared by placing small fragments of pine or spruce wood in concentrated sulfurous acid and calcium chlorid, as a result the cellulose is set free and the solution absorbs the ethereal oils and the mineral constituents. Practically, however, the active constituent is SO₂. This fluid for therapeutic purposes is placed in receptacles that expose a great surface to the air, and if necessary, it is agitated to promote vaporization. It was originally claimed that it had some disinfectant qualities, but a series of experiments with microorganisms showed that it was necessary for it to exist in the atmosphere to at least 1% in volume in order to destroy them. And this degree of concentration cannot be supported by human beings. It is not absorbed to any considerable extent by the blood, and even if such were the case, it could not be sufficiently concentrated in the tissue to have any antibacterial action; on the other hand it is an excellent expectorant, both in the lower animals and in human beings, causing, when applied directly to the trachea of cats at first an increased quantity, and then greater ease of expectoration. Upon the respiration it causes first increased frequency and then slowing and greater deepness, corresponding to the action of sulfurous acid. In cases of phthisis it seems to render the sputum more fluid. It appears to have no effect upon the general metabolism, but is particularly applicable to patients who have a severe depressing cough, with small quantities of viscid mucous sputum. It is not contraindicated by hemoptysis nor fever, and is possibly of benefit in laryngeal tuberculosis. The therapeutic dose varies from .001 to .005%. Its toxicology is the same as that of sulfurous acid. It irritates the mucous membranes, and may cause ulceration; it produces disturbance of respiration, and may even cause pulmonary edema. [J.S.]

16.—Brosch describes a specimen removed from a man of 63, who, in spite of progressive ossification of the costal cartilages, had the chest-type of respiration. The cartilages of the trachea at either end were turned outward instead of inward, giving to the trachea an exceptional breadth and considerable circumference; although the lumen was diminished, the bronchial cartilages had an oval form and were considerably enlarged, so that the circumference of the main bronchia was about 7 cm., although the lumen was actually diminished. Brosch suggests the name of "**dilatatio paradoxa**." The costal type of respiration was necessary in this case, because the depression of the diaphragm would have served to diminish the lumen still more, by exerting tension upon the air-channels. [J.S.]

17.—Langowoy has studied a number of cases suffering from various diseases such as croupous pneumonia, typhoid fever, chlorosis, tuberculosis of the lungs, nephritis, cirrhosis of the liver, pleural exudate, and various forms of cardiac disease in order to determine the **change in pulse-rate** that occurs as a result of **alteration in position**. He concludes that the increase in pulse-frequency that occurs in health in changing from the horizontal to the vertical posi-

tion, can be explained by the increased muscular effort to hold the body in a vertical position, by the decrease of the arterial and intracardiac pressure upon the cardiac ganglia, and by the decrease of intercranial pressure that diminishes the action of the inhibitory centers of the medulla. During convalescence this change in pulse-frequency is increased on account of the greater difference in arterial pressure produced by the loss of tone in the vessels. In cases of cardiac or vascular disease, the alteration in pulse-frequency follows the normal type unless the cardiac ganglia have suffered a diminution of irritability; this rarely occurs except when compensation is disturbed, and in such cases the symptom of decrease in pulse-frequency upon assuming an erect posture is a sign of gravest importance. [J.S.]

18.—Grober has made a literary and experimental study of the route by which infecting microorganisms may reach the pleura. The most important routes are, of course, the blood and lymphatic systems. Microorganism may readily pass through the mucous membrane of the bronchi to the pleural cavity. This Grober has proved by injecting slowly into the bronchial system of a small dog, a considerable quantity of a liquid holding a pigment in suspension. This was accomplished without causing dyspnea. The animal was killed almost immediately, and the pigment found in the lymphatic tissue of the mediastinum, and in the visceral and parietal pleural surfaces. A repetition of this experiment gave similar results. He then discusses the probability of infection from the mediastinum, through the diaphragm, and particularly through the lymphatic system. It is probable that many cases of tuberculous pleurisy are secondary to scrofulosis, and the pleura is probably a route by which the bacilli reach the lung. Infection may also take place from the tonsils; for an injection of a suspension of india ink into the tonsils of 2 dogs caused deep pigmentation along the peribronchial lymphatics, and of the mediastinal and subpleural lymphatic glands. [J.S.]

19.—Hirsch continues his study of the relation between the heart muscle and the muscles of the body. In this article he discusses the effect of obliteration of the pericardium, valvular disease, and chronic disease of the respiratory organs. The results are given in convenient tabular form. He concludes that the different portions of the heart may hypertrophy entirely independent of each other. In arterial sclerosis, hypertrophy only occurs if the bloodvessels of splanchnic viscera or of the aorta above the diaphragm are involved. It is probably desirable to differentiate between atheroma of the abdominal vessels and commencing interstitial nephritis. Renal disease usually causes hypertrophy of the entire heart; it is probably the cause of the so-called "beer heart," Hirsch never having seen a case of the latter in which nephritis did not exist. The condition of the heart in cases of vascular hypertrophy, is not yet clearly understood; obliteration of the pericardium will not cause cardiac hypertrophy; if hypertrophy of the left ventricle occurs in mitral disease, it is due entirely to mitral regurgitation, and never to stenosis. The auricles in mitral stenosis and in relative inuspid regurgitation hypertrophy in accordance with the amount of work they are called upon to perform. In pulmonary diseases such as emphysema, pleural adhesion, and in some cases of tuberculosis, hypertrophy occurs in the right ventricle; in cases of kyphoscoliosis there is a hypertrophy of the right ventricle that accords roughly with the degree of vertebral deformity. Often there is a simultaneous atrophy of the left ventricle. The latter is probably explained by the diminished work it is called upon to perform, as a result of the gradual impoverishment of the blood in consequence of the chronic venous congestion. This in contrary to Cohnheim's opinion, who believed that a weak right ventricle ultimately caused hypertrophy of the left ventricle, because in these cases clinical experience shows that the symptoms of insufficiency in the right heart have usually occurred for a long time. [J.S.]

20.—Koster has undertaken a systematic study of the clinical phenomena of paralysis of the facial nerve; he has collected 41 cases in the last 2 years, which he classifies as follows: 1. Those in which the lesion was situated outside the stylomastoid foramen. 2. Those in which the lesion was situated in the petrous portion of the temporal bone, which he subdivides into: (a) In the lower portion of the fallopian canal; (b) in the fallopian canal above the tympanum; (c) in the portion of the canal extending from

the porus acusticus internus to the geniculate ganglion. 3. When the lesion was situated in the extracerebral and intracranial portion of the nerve. 4. Paralysis following fracture of the temporal bone. Bilateral congenital paralysis (nuclear lesion). In the present article he discusses, particularly, the effect upon perspiration; in 23 cases this was diminished upon the paralyzed side; in 6 it was increased, and in 7 cases, although there were no objective disturbances, the patient experienced a subjective sense of dryness, or moisture. In several cases the restoration of the function of the sweat glands had occurred before the first examination. In 2 cases in which there was nuclear disease, the perspiration was greatly diminished on both sides, and in a case of progressive bulbar paralysis this same condition was present. The relation of the secretion of sweat to the electric condition of the muscles is shown in another table; in only 5 of the 38 cases was the reaction of degeneration complete. In other cases in which the reaction was present, perspiration was not altered. An interesting observation was, that in 2 cases the secretion of sweat was still disturbed long after the electric reactions were normal; although in the majority of cases in which this symptom was observed (10 out of 14) recovered earlier. The diminution is probably due to paralysis of the excitomotor fibers; when the secretion is stored there is probably a collateral innervation through the trigeminal fibers. [J.S.]

21.—Strauss defends the work of Basch against the attack of Strassberger. He admits that the technic differed in some respects from that devised by Schmidt and Strassberger, but claims that the errors thus introduced were insignificant. [J.S.]

22.—Frese reports the case of a man of 26, who, 4 weeks before admission to the hospital had pain in the stomach, and 2 weeks later experienced severe pains in the bones, and noticed rapid emaciation. When admitted to the hospital an examination of the blood revealed a considerable reduction in the red-blood cells and hemoglobin; this continued until his death, 9 weeks after the first symptoms. Toward the end there was a slight leukocytosis. At the autopsy a carcinoma was found at the pylorus that had given metastases to the lymph-glands, lungs, and the medulla of the bone. Also the case of a woman of 28, who had suffered from gastric disturbances for 9 months. An operation revealed the presence of a pyloric carcinoma with metastasis of the adjacent lymph glands, a gastroenteric fistula was made, and the patient temporarily relieved. She gradually developed a profound anemia, from which she died. At the autopsy metastasis to the bones was discovered. In both cases the alterations of the blood resembled those of progressive pernicious anemia. In the first case the patient had high fever, which Frese ascribes exclusively to the neoplasm; in the second case an interesting feature was the presence of an enormous number of the eosinophile cells and eosinophile granules in the spleen; this was probably a myeloid alteration similar to that which occurs in leukemia, although leukemic alterations were not observed in the bone-marrow. [J.S.]

Intussusception in Children.—Primrose (*Canadian Journal of Medicine and Surgery*, November, 1900), says this is the most frequent single cause of intestinal obstruction, constituting probably $\frac{1}{3}$ of all the cases of obstruction in children. The cause is not known, but is probably due to some local irritation which starts a peristaltic action of the bowel, limited to a certain portion of the gut, and thus the passive portion is invaginated into the active portion. The occurrence of intussusception in the dying is a remarkable fact, and according to one authority it is found in $\frac{1}{3}$ of the cases coming to postmortem. The symptoms are usually characteristic, but are sometimes obscure. The peculiar pain which becomes gradually more intense and then subsides, vomiting, the mucous stools stained with blood, and the sausage-like tumor are usually found. The author reports 3 cases. In 2 of these the intussusception occurred at the ileocecal junction, and in the third there were multiple points of intussusception from 1 to 2 feet below the duodenum. In each of them inflation by air was performed, but without success. The author is not favorable to the inflation method since it often does not accomplish the desired object and is also attended with danger. Laparotomy was performed in each of these cases. Two of the children recovered, but the one with multiple intussusception died. [A.B.C.]

Original Articles.

THE DIAGNOSIS OF CALCULOUS DISEASE OF THE KIDNEYS, URETERS, AND BLADDER BY THE RÖNTGEN METHOD.¹

By CHARLES LESTER LEONARD, A.M., M.D.,
of Philadelphia.

THE development which has lately taken place in methods of physical diagnosis greatly facilitates the differential diagnosis of renal disease. Pathologic processes in other organs can be readily excluded, while the differentiation is being rapidly made between the various forms of renal disease that simulate each other very closely in their symptomatology.

The centrifuge, the segregator, the ureteral catheter, and the cystoscope are factors that have aided greatly in this development. The separate urines can be collected and a chemical and microscopic analysis be immediately made of each specimen. When these are combined with a thorough cystoscopic examination, the region of the lesion can be very closely determined, and the functional efficiency of each kidney, and the extent of its involvement in the pathologic process estimated. Bacteriologic examinations are valuable adjuncts, but as yet the positive results are the only ones upon which much dependence can be placed.

Each of these methods has its peculiar advantages and adaptations, each has its disadvantages. They form the parts of a whole and are each of intrinsic value and are complementary of the others. No one of these methods is as valuable by itself as when supplemented by the others. All have their appropriate place in the diagnosis of renal diseases and in estimating the amount of injury that has been done to the kidney.

In suspected calculous disease the analysis of the separate urines should always be made when possible. The cystoscopic examination of the bladder is also very valuable. Lesions of the bladder can be detected or eliminated. The character, quantity and regularity of the urinary flow can be observed. When calculi have been found in the kidney or ureter by other methods, the cystoscopic examination will determine whether the impaction produces complete or partial anuria on that side. This can also be determined by catheterizing the ureter, by using the segregator, or can be inferred from the presence or absence of a hydro-nephrosis, if the condition has been present for some time. The persistence of pain or the recurrence of attacks also show that the urinary flow has not been completely obstructed.

Next to the Röntgen method the ureteral catheter or sound has given the most reliable information regarding calculi. Albarran has had considerable success in employing it, but has recorded his failures and disbelief in its accuracy, although appreciating its value. Kelly has successfully detected calculi in this way, and by coating the tip of the catheter with wax has observed the scratches which the calculi produce. This method is valuable in confirming the results otherwise obtained, and should be employed wherever feasible. It cannot be considered absolutely accurate, as calculi imbedded or encysted in the kidney would not be touched. It is particularly adaptable to ureteral calculi, and besides

confirming other observations may serve to dislodge a small calculus or push it up into the pelvis of the kidney.

Bigelow's evacuator is very serviceable in finding these small calculi that have passed into the bladder but no further. An examination with it should always precede operation for the removal of a small ureteral calculus that has been detected by the Röntgen method, especially if any interval intervenes between its detection and the operation, or if massage has been employed in the attempt to dislodge it. This is equally true of all operations for the removal of foreign bodies. Operation must follow immediately after the localization or the localization must be repeated. Immobilization is always essential during the interval.

The Röntgen method of detecting or excluding calculi from the kidneys and ureters has proved itself to be absolutely accurate, when applied with the requisite technic. The errors which have been noted were all due to defective technic or inexperience in reading the negatives. The absolute negative as well as the positive diagnosis of calculous disease is feasible. It depends solely upon the production of negatives having detailed shadows of tissues less opaque than the least opaque calculus. When such a negative is obtained and correctly read no error can be made.

Twenty cases in which calculi of all sizes and chemical composition have been detected in the kidneys or ureter, attest its value. Among these are 6 in which calculi were found in the ureter; 4 in which multiple calculi were found, and 2 in which calculi were found on both sides. Not only have these positive diagnoses been confirmed, by the passage of calculi, by operation, and by postmortem examination, but the negative diagnoses have also been found correct in every case but one, in which the error was due to defective technic. The majority of these cases have been previously reported (*Annals of Surgery*, February, 1900) in conjunction with a description of the technic employed.

The advantages which this method possesses are its mathematical accuracy, and comprehensiveness. The equal value of the negative and positive diagnoses. The ability to detect calculi in their incipency before serious injury has been done to the functional efficiency of the kidney, and when the freedom from infection makes an aseptic operation possible. The dangers that threaten when a small quiescent calculus is present can thus be avoided, as well as the dangers of operating upon the wrong kidney; upon one without knowing the other is the seat of calculus; or of leaving a calculus behind by an incomplete operation. The operative interference is localized and limited to a very small area facilitating the operation and avoiding needless injury and traumatism to other portions of the urinary tract. Thus a calculus weighing 42 grains was located in the upper pole of the kidney and removed through a small incision directly down upon it, that barely admitted a finger. A small ureteral calculus was located just within the pelvic brim where it was found by bimanual palpation. It was removed by a transperitoneal ureterolithotomy, and proved to be a uric-acid calculus of the mulberry type which weighed $2\frac{3}{4}$ grains. A second ureteral calculus was removed per vaginam. A ureteral catheter was introduced and the vaginal wound packed, both packing and catheter were withdrawn on third day with perfect healing. This ureteral calculus was apparently a phosphate stone and weighed

¹ Read before the Surgical Section American Medical Association, Atlantic City, June, 1900.

27 grains. A large calculus of the same character was removed from this patient's other kidney. It was broken and could not be weighed. It was phosphatic in composition, and measured over 2 inches in length. On the side where the ureteral calculus was found there was a large hydronephrosis, on the other a pyonephrosis. Other cases have been previously reported where encysted calculi were detected, and where multiple calculi were removed and the completeness of the operation assured.

Such advantages clearly demonstrate the superiority of this method over exploratory nephrotomy or any other method of diagnosis. It is free from all danger and inconvenience, and is more accurate. The absolute negative diagnosis renders treatment rational that would otherwise be hazardous. The danger from sudden impaction and anuria is always present so long as a calculus remains in the kidney, the renal pelvis, its calyces or the ureter. It has also been shown that bacterial infection is far more liable to take place in a kidney that is the seat of calculous disease or where the ureter is partially obstructed.

The detection and accurate localization of the calculus, in cases of unilateral or complete anuria due to calculous disease, is of the utmost importance in directing and limiting the operative intervention. Complete anuria is readily recognized, but the localization of the seat of obstruction, although of the greatest moment, has hitherto been a most difficult problem, uncertain of a correct solution.

Unilateral anuria can, of course, be easily recognized by employing the segregator, the ureteral catheter, or the cystoscope. This condition has, however, been frequently overlooked, and the cessation of symptoms attributed to the passage of or dissolving of the calculus and the credit given to the medicinal agent employed. The symptomatology of the processes is identical, but their pathology and results are vastly different. One leads to the recovery of full functional activity, the other, to atrophy and degeneration of the kidney with complete loss of function. Postmortem examinations and the results of operation upon the other kidney under these conditions show how frequently they escape detection.

Many of the recoveries attributed to this or that medicinal agent are founded on an incorrect diagnosis of the presence of calculus. Many others are in reality impactions with the establishment of unilateral anuria and the subsequent destruction of the kidney. In others the calculus becomes quiescent and the trouble recurs at a later period, after infection has taken place and greater injury has been done to the kidney.

With the possibility of such grave dangers as these in view, unless a calculus has been passed and recognized, or can be found in the bladder by a Bigelow's evacuator, or by some other means, a patient who has suffered an attack of renal colic should be examined for calculus. The question of unilateral anuria can be settled by the segregator, or the ureteral catheter, but calculus can only be detected or excluded with certainty by the Röntgen method properly employed.

The patient should be given the advantages of these methods of examination before nonoperative treatment is decided upon. Without them he is exposed to the immediate danger of the loss of one kidney, and the future dangers that surround the presence of a quiescent calculus in the kidney. The advantages that are derived from early diagnosis and operation should never be forgotten. This early diagnosis can be made in all

of these cases, as soon as a suspicion points to the presence of a calculus.

A glance at the symptomatology of diseases that may be mistaken for calculus, shows that it is impossible to deduce from them conclusions that would even exclude conditions purely outside of the kidney. A differentiation between the intranephritic pathologic processes and including those involving the ureters, requires all the aids which modern methods of physical diagnosis can command, and even then has its limitations.

The variations in symptomatology, illustrated by the 20 cases in which calculi have been found in the kidneys and ureters, are very great. In some the typical renal colic was present, followed by vomiting or a chill, while the results of the urinalysis were typical; in others one or other symptom was wanting; the pain was a dull diffused ache in the lumbar region, and the urine was frequently normal, except for a microscopic trace of blood; in others an indefinite lumbar pain, a persistent trace of albumin, and occasionally a few pus-cells were all that directed suspicion to the kidney.

The two cases that belong to this latter group are of particular interest, as they illustrate cases that might have been readily mistaken for chronic nephritis. In fact one had been treated as such at various periods during the 20 years in which the albuminuria had persisted. In neither case had there ever been any characteristic symptoms of calculous nephritis. There was an early history of a trace of blood in each case, but it did not excite suspicion, nor had it ever been noted since.

Such a marked range of symptoms shows how readily cases of calculous disease may be mistaken for other conditions and escape detection. Many cases that are apparently the result of entirely different pathologic processes will be proved to be calculous nephritis, if they are examined by the light of this new method. The negative diagnosis in such cases would render other than operative treatment rational, while the positive furnishes the indication for operation with all its advantages. Thus a harmless examination will make relief possible at an early period, in cases that would otherwise have drifted on until a more critical condition demanded intervention, and yet rendered it more hazardous. Examples like these accentuate the value of the negative diagnosis and show its utility, even in cases where a negative diagnosis by other methods is apparently accurate.

The 8 cases of operation in which a negative diagnosis for calculus had been given show how close is the similarity in symptomatology that so often demands operation when no calculus is present. The Röntgen method determines with absolute accuracy the presence or absence of all calculi in every case in which a satisfactory negative can be secured, if that negative is correctly read. It does not preclude the employment of exploratory nephrotomy, as there are many conditions that simulate calculous disease, that can be differentiated or relieved in no other way. It does, however, preclude by a negative diagnosis exploratory nephrolithotomy, or the actual incision into the kidney in the search for calculi. Unless some macroscopic pathologic process clearly indicates the necessity for incision it should be avoided. On the other hand a number of cases have shown the value of the Röntgen diagnosis in detecting calculi that the exploratory operation would have missed, since it was the only indication for incising a kidney that appeared normal.

The mechanical accuracy of this method is very great. Errors can creep in through faulty technic or lack of skill in reading the negatives. Where, however, the negative secured fulfils the requisite conditions, the experienced eye can detect or exclude all calculi. In some cases it may be as yet impossible to secure negatives with such detail, as in very corpulent or muscular subjects. The majority of failures and errors reported should, however, be attributed to a lack of skill or a faulty technic on the part of the operator and not to any inaccuracy in the method, or the inability of the Röntgen-rays to produce accurate negative or positive diagnosis. This is equally true of the errors that have been frequently attributed to this method of diagnosis in dealing with other surgical problems. The defects are not in the method, but in its inefficient and ignorant employment by those deficient in technic. These elements should rapidly decrease as the sources of error are recognized and the technic of the method is developed. They are common to all methods depending upon the acquirement of skill in making observations with accurate instruments.

Although the detection of vesical calculi is generally very easy by the ordinary methods employed, there are applications of the Röntgen method that are very valuable. These have been illustrated by the detection of encysted and multiple calculi, the determination of the presence of calculus in conjunction with an enlarged prostate, or where there is any other mechanical hindrance to the proper employment of the vesical sound.

There are other applications of this method in the detection of pathologic processes that involve the kidneys and bladder, that will develop by the future progress in the differentiation of tissues. They have only been indicated by the negatives that show the outline of the normal or hydronephrotic kidney or of the enlarged prostate. The perfection of a technic that will render their differentiation positive and accurate in all cases will greatly increase the value of this method in renal diagnosis.

ACUTE INFECTIVE ENDOCARDITIS FOLLOWING VACCINATION; RECOVERY.

By WARREN COLEMAN, M.D.,

of New York.

Professor of Clinical Medicine in Cornell University Medical College; Assistant Physician to Bellevue Hospital.

THE patient, a female, aged 23 years, gives a good family history and is in excellent physical condition. She had pertussis, varicella, and measles in childhood, but has had no serious illness since her tenth year. She has never had rheumatism. During the past year she has had two attacks of tonsillitis, but is unable to tell of what nature they were. From the interval of time elapsing since the last attack it apparently has no connection with the present illness.

Two months ago the patient was vaccinated. Extensive cellulitis developed and the axillary glands became involved. The vaccination wound is not yet healed but is clean. The patient has had a slight cough for a week.

The present illness began on February 18, —. The patient feels weak and feverish. She complains of small areas of tenderness on the arms and legs, chiefly about the elbows and knees. The areas are swollen and red. On the following day the patient had two chills, followed by profuse sweating. The knees and ankle-joints have become tender and give pain on the least motion.

February 21.—*Physical examination.* The patient is well nourished, though anemic, and has a distinctly septic appearance.

Lungs—negative.

Heart: There is throbbing of the vessels of the neck. The size of the heart is normal. A soft systolic mitral murmur is present, with accentuation of the pulmonic second sound.

Extremities: Numerous patches of erythema nodosum are found on the extensor surfaces of the arms and legs, mostly about the elbows and knees, but also extending down the anterior surfaces of the tibiae. The patches vary in size from a pea to a silver dollar. They are inflamed, infiltrated, elevated, exquisitely tender, and have a brawny appearance and touch. No fluctuation can be detected. The ankle and knee-joints are painful on motion and joint-pressure. There is neither swelling nor redness, however.

February 22.—The patient had a chill last night followed by profuse sweating. The cutaneous inflammatory processes are resolving, and, it may be added here, resolution proceeded without suppuration in any of the areas. Each patch, however, remained as a stain for some days, passing through the colorings of oxidizing hemoglobin. The pain and tenderness have left the ankles, but are still present in the knees. The right wrist has become tender and motion gives pain, but there is no external evidence of inflammation. The area of cardiac dulness has increased to the right of normal.

February 24.—The nurse states that the patient sweats freely, especially when asleep. February 25.—The pain and tenderness have disappeared from all the joints but the right wrist.

February 26.—The patient had a chill last night followed by profuse sweating. Roughening of the aortic second sound is detected at today's examination. February 27.—The pain and tenderness have disappeared from the right wrist.

February 28.—Roughening of the aortic second sound is more marked today. March 1.—A distinct systolic murmur is heard over the aortic area. March 2.—The patient's general condition is not so good. Both murmurs are pronounced. The heart-dulness has increased still further to the right. The pulse is weaker. March 5.—The patient had a chill, followed by sweating. Sweating is not as troublesome as in the early part of the illness. March 6.—The patient complains today of pain and tenderness in the left wrist. There is no external evidence of inflammation. The pulse has become intermittent. Pulsation in the carotids is very pronounced.

During the three days from the 6th to the 9th the pulse became very irregular and intermittent and the arteries lost tone. The cardiac murmurs remained unchanged. March 10.—The pulse has become still more irregular and intermittent. Since yesterday, the right ventricle, which had been slowly dilating, has dilated acutely and without exertion on the part of the patient. The cardiac dulness now extends an inch and a half to the right of the sternum. From the 10th to the 13th the patient's condition remained unchanged. March 14.—The pulse has begun to improve. The morning pulse is fairly regular, while the afternoon pulse is irregular and intermittent. March 15.—The general condition begins to improve. The patient is bright and the pulse stronger. March 20.—The cardiac dulness is diminished, but the murmurs are still pronounced. March 25.—The murmurs are not so pronounced. The pulse is slower, regular, and of fair tension. The cardiac dulness still extends to the right of the sternum, but is diminishing. March 29.—Cardiac dulness has diminished still further. The mitral murmur is distinct; pulmonic sound accentuated. The aortic murmur is present but is not so loud. The patient is gaining flesh. April 1.—The aortic murmur has disappeared, though the mitral murmur remains.

At this time the patient passed from under my observation.

The temperature-range during the patient's illness was low, running during the first two weeks from 100° F. to 101°—102° F. The highest temperature reached was 103.8° F., on February 24. During the last four weeks of the illness the temperature fluctuated on either side of 99° F.

Albumin was found in the urine at only one examination, and then in only small quantity, though it was repeatedly looked for. The specific gravity of the urine was persistently low, though the quantity was not increased above normal; thus, with 44 ounces, in 24 hours, the specific gravity was 1.006.

Unfortunately an examination of the blood was not practicable.

The Widal reaction, performed at the laboratories of the Board of Health, was negative.

The diagnosis of infective endocarditis, due to vaccination, is based on the following points:

1. The septic arm, which could serve as a focus of systemic infection.

2. The presence of a mitral murmur. (It may be added, that the patient's heart had been examined a few months previously and found normal.)

3. The coincident appearance of patches of erythema nodosum on the arms and legs.

4. The septic appearance and septic symptoms,—chills and sweating.

On examining the heart about 2½ years after the attack the cardiac outline was found normal, with no evidences of either a mitral or aortic murmur. The arterial tension, however, was a little high and the aortic second sound somewhat accentuated, but this may have resulted from the excitement attendant on the examination.

The necessity of concealing the patient's identity compels me to omit mention of the name of a colleague, without whose careful bedside notes this report could not have been made.

THE USE AND ABUSE OF ZOOLOGICAL NAMES BY PHYSICIANS.

By CH. WARDELL STILES, Ph.D.,

of Washington, D. C.

Zoologist, U. S. Bureau of Animal Industry; Secretary of the International Commission on Zoological Nomenclature.

WHEN as a zoologist I am called into consultation by a physician or requested to make a microscopic examination for him, it is not unreasonable for him to maintain that in all my relations to the case in hand, I should feel myself bound by the code of ethics recognized by the medical profession. In other words, for the time being, I act in the capacity of a medical consultant and hence should submit to any rules and regulations adopted by the majority of medical practitioners and investigators for the guidance of medical workers at large. And if I divulged professional secrets obtained in consultation, it is very doubtful whether physicians would acknowledge it as a valid excuse were I to advance the claim that I was not acquainted with professional customs. It would be replied that I should inform myself of those customs before laying myself subject to them.

These principles I, as a zoologist, unreservedly admit and endorse. At the same time, it may be permitted to submit, that this is a day of reciprocity, and if zoologists who deal with medical matters are quasi-members of the medical profession, hence subject to the rules and regulations which govern that profession *sensu stricto*, then, conversely, physicians who deal with zoological matters become for the time quasi-zoologists, and should submit themselves to the rules and regulations of the zoological profession; and it does not seem extreme to maintain that before dealing with a zoological subject publicly, it is incumbent upon them to inquire into the zoological customs involved.

In connection with the principle here advanced, I desire most respectfully—but at the same time not with-

out emphasis—to direct attention to the abuse made by physicians of zoological names. To my regret, it is necessary to even go so far as to state that members of the medical profession, in their well-intending and most laudable object of advancing the knowledge of their colleagues, not infrequently, and, as I feel convinced, unintentionally, adopt customs which are strictly unzoological and which result in no inconsiderable amount of inconvenience, irritation, and confusion to their zoological friends and admirers.

In medicine, the terminology is more or less subjective, and based upon authority, without being bound by any regularly adopted national or international rules. In zoology, on the other hand, the nomenclature is objective, based upon priority instead of authority, and subject to certain iron-clad rules and regulations, the result of a century and a half of study, and adopted by the national and international congresses; they are known as the Code of Nomenclature.

Now, it can hardly be maintained by zoologists that all physicians should be familiar with the numerous intricacies of these rules. It would, however, seem probable that those physicians who are accustomed to publish original articles would have at least one systematic zoologist among their friends who could advise them upon the points involved.

Unfortunately, physicians too frequently take liberties with our technical names. If a name does not appeal to them as being especially euphonious, or as applicable, they change it. If they are not pleased, for any reason, with the spelling of a zoological name, they change that also. They do not stop to consider that in dealing with zoological objects and names, they are for the time being quasi-zoologists, and before changing a name in this manner, it is incumbent upon them to inquire whether such an alteration is in accordance with the best usages in zoology.

To take a few examples: The hydatid (*Echinococcus*) is suffering with no less than sixty names; the common unarmed tapeworm (*Taenia saginata*) has about forty names.

This multiplicity of designations is due very largely to the fact that physicians unnecessarily change names. Now, the changes in nomenclature, connected with the advance of our knowledge of classification, is extensive and regrettable enough, without any unnecessary alterations, due to the pure caprices of individual taste.

Again, it is now becoming more or less *à la mode* to simplify the spelling of medical terms. We now frequently write *diarrhea* instead of *diarrhœa*; *hemoptysis* instead of *hæmoptysis*; *amebic* dysentery instead of *amoebic* dysentery. So long as the medical profession desires to simplify the spelling of its own terms, I have no criticism to offer, and am willing to follow the decision of the majority, if a majority can be obtained; but as soon as physicians extend their orthographic reform to zoological names and do so in direct contradiction to the international zoological code, I most respectfully, but also most vigorously, protest.

Thus: *amebic* (amibic or amoebic) *dysentery* is a medical term, and may be written by the medical profession as it sees fit. *Amiba coli* is the technical name of a zoological object; to determine how this word shall or shall not be written, is a prerogative of the zoological and not of the medical profession. According to the International Code, it should be written *Amiba coli* or *Amoeba coli*; yet it has become more or less fashionable in medical writings to adopt *Amœba coli*. Again, the

name of the hydatid is written *Echinococcus*, yet some of our reformed spellers in medicine change this to *Echinokokus*. Some medical authors adopt for *Taenia saginata*, the spelling *Tenia*, *Tenea*, or *Tinea*.

These changes in spelling may appear mere trifles to the physician-author, yet I can assure him that they are nothing less than exceedingly exasperating to the zoologist. Our righteous indignation on this point has its basis in the following facts:

In zoology we are dealing with several million systematic names. Every genus must have a distinct generic name, and every species in a genus must have a specific name distinct from the name of every other species in that genus. Under these circumstances it will be readily understood that we have been forced to adopt rigid rules governing the use of these names, since otherwise we would soon become swamped in a chaos of Latin words.

Taenia to us is the name of a genus of tapeworms and was proposed in 1758 by Linnaeus. It is now proposed by our spelling-reformers to simplify this to *Tenia*. *Tenia* might be to us, however, a totally distinct animal; it might perhaps be the name of another worm, or of an insect, or of a snake, etc. Some medical authors prefer *Tinea*, but to us *Tinea* is the name of a genus of lepidoptera (the clothes moth *Tinea pellionella* belongs here) proposed by Fabricius in 1775. Still other medical authors have written *Tenea*, but to us *Tenea* is a genus of mollusks proposed in 1875. Again, Ehrenberg proposed the name *Amoeba* in 1830 for a genus of protozoa into which *Amoeba coli*—the organism associated with amebic, amibic, or amoebic, dysentery—has been placed. Our spelling-reformers wish to simplify this to *Ameba*, and they speak of *Ameba coli*. *Ameba* might, however, be the name of a totally distinct genus, and no end of confusion might arise by adopting *Ameba* for *Amoeba coli*. This case is one which is particularly in point. It has been quite generally overlooked that Ehrenberg was a spelling-reformer, and that his generic name *Amoeba* 1830 is simply a changed form of the word *Amiba*, proposed by Bory in 1824. The word comes from the Greek ἀμύβη, and should have been translated into Latin as *Amoeba*. But it was not so transcribed at first, and the rendering adopted depends upon the stand taken upon "emendation."

One school of zoologists, known as the American school, maintains that the original spelling, good, bad or indifferent, should be adhered to, and in this event, *Amiba* should be accepted instead of *Amoeba*. To this school belong the vast majority of American systematic zoologists; also the majority of systematic ornithologists of the world, and the minority of the other systematic zoologists of Europe.

Another school, known as the "Purists," would agree with Ehrenberg, and correct the spelling to *Amoeba*, rather than adopt *Amiba*. This view is held by a small minority of systematic zoologists in America and by the majority of zoologists in Europe.

Accordingly, one has zoological authority for adopting either *Amiba coli*, or *Amoeba coli*, but there is not one iota of defense in zoological rules, regulations, or customs, of any land, for the name *Ameba coli*. Personally I am uncompromisingly in favor of *Amiba coli*, and I maintain that any other spelling, such as *Amoeba*, is contrary to the law of priority. While as for *Ameba coli*, its use is calculated to make confusion more confused; it has no zoological authority, and should not be adopted.

Many other cases could be mentioned, but these are sufficient to show the object of this paper, namely to support the thesis:

It is incumbent upon physicians to follow zoological customs in dealing with zoological subjects, as it is incumbent upon zoologists, to govern themselves by the code of medical ethics in dealing with medical cases.

PRIMARY CARCINOMA OF THE PANCREAS, WITH REPORTS OF FOUR NEW CASES.*

By FREDERICK A. BALDWIN, M.D.,

of Ann Arbor, Mich.

Assistant in Pathology at the University of Michigan.

[From the Pathological Laboratory of the University of Michigan.]

OF all the diseases of the pancreas, carcinoma, both primary and secondary, is the most common; *e. g.*, Ancelot¹ found that 59.7% of all diseases of the pancreas were carcinoma. From September 1, 1894, to September 14, 1897, Benda¹ made 3,018 autopsies and noticed that the pancreas was affected in 79, of which 8 were primary and 12 were secondary carcinoma of the pancreas. From 1868 to 1886, Segre¹ made 11,472 autopsies, and in 127 of these carcinoma of the pancreas was noted. Rhoda,¹ of the Pathological Institute of Kiel, found 13 carcinomas of the pancreas in 234 autopsies in which the pancreas was examined. But all these observers, except Benda, have not differentiated primary from secondary carcinoma, so that when Miralle¹ worked up this subject in 1893, he found only 113 cases then reported and he was not fully convinced that 7 of these were genuine.

Regarding the frequency of primary carcinoma of the pancreas as compared to primary carcinoma elsewhere, Willigk¹ found carcinoma of the pancreas in 22 cases of a series of 467 autopsies on patients dying from carcinoma, and Biach,¹ who made 18,069 autopsies from 1869 to 1879, noticed 22 carcinomas of the pancreas in 1,270 cases dying from carcinoma. Of the 5,565 autopsies made at the Wildener Krankenhaus in Vienna between 1857 and 1866, 6 primary carcinomas of pancreas were described in the 514 autopsies on carcinomatous subjects. Of the 477 autopsies made at the Rudolf's-spital, 221 were upon carcinomatous subjects and one primary carcinoma of the pancreas was noted.

Etiology.—In general, primary carcinoma of the pancreas does not differ from primary carcinoma of other organs. According to most authors, it occurs more frequently in males than in females. Benda found 5 of his 8 cases were in females; Miralle, 69 of the previously reported cases were in males; Segre,² 62% in males; Bigsby,³ 16 males to 12 females; DaCosta,³ 24 males in his 37 cases, and White makes the radical statement that two cases are found in males to one in a female. Besides all these reported cases, I have had access to about 50 more which I have found in the literature by means of the *Index Medicus* and which I have analyzed. Of these, 33 were reported as having occurred in males. As to the age in which primary carcinoma of the pancreas occurs most frequently, one may say that it is between 40 and 60. In Bigsby's cases, 14 were over 40 and all the females were over 50. In Benda's cases the average age for the males was 56 and for the

³ Ziemssen: Encyclopedia of Practice of Medicine, vol. III.

females 55½. The average age of the 50 cases I analyzed was 50, but I found one primary carcinoma of the pancreas reported in a female aged 26, by Fothergill,⁴ another in a male aged 24 by Bruen,⁵ another in a male aged 23 by Satterthwaite,⁶ and 4 between 30 and 40. Kühne in Körte's work on the pancreas is reported as having found a primary carcinoma of the pancreas in a child aged 12, Simon another in one aged 4, and Litten another in a newborn. Though he reports them, he discredits them as being bona fide cases of carcinoma.

Morbid Anatomy.—Primary carcinoma of the pancreas is found most frequently in the head, next in the body, and least often in the tail of the pancreas. In Benda's cases he was able to point out positively that the carcinoma arose in the head in 2 cases, in the body in 2 more, and of the others he was not sure. Of the 57 in which Segre could state the origin definitely he noticed that 35 arose in the head, 2 in the body, 1 in the tail, and 19 were diffuse. Miralle found that 83 of his 113 cases arose in the head, and Boldt pointed out that 23 of his 53 cases had their origin in the head of the organ. In my 50 analyzed cases I found the primary seat of the growth reported in the head in 24 cases, in the body in 3 cases, in the tail in 5, diffuse in 4, while in the others it was not stated.

Regardless of the situation of the tumor mass, primary carcinoma of the pancreas may arise by atypical cell-proliferation either from the epithelium lining the collecting ducts, or the acinous cells or the epithelial cells of the areas of Langerhans. In some of those arising from the epithelium of the ducts, we infer, from similar conditions found in the gallbladder, that prolonged irritation from calculi may be an important factor. Of my 50 cases only 1 was reported in which a calculus was noticed. This was reported by Suckling.⁷ As in carcinoma found elsewhere, the direct cause of the cell-proliferation in all cases except, perhaps, that just mentioned, is not known.

It is interesting to note here that those carcinomas arising from the areas of Langerhans usually pass through the stage of adenoma. The usual form of primary carcinoma as it is reported is the scirrhus, though few medullary carcinomata and adenocarcinomata are reported. Secondaries are not common except in the neighboring lymph-glands and in the liver. In my 50 cases no metastases were found in 10 cases, metastases were found in the liver 11 times, in the neighboring lymph-glands 11 times, in duodenum 5, in lungs 3, in kidneys 3, once in the right kidney alone, and once in the left kidney alone, spleen 3, capsule of spleen alone 1, opening of the common duct into the duodenum 2, pleura 2, omentum 2, colon 2, solar plexus and nerves 2, mesocolon 1, muscular coat of the intestine 1, abdominal wall 1, pyloric wall 1, opening of the cystic duct from the gallbladder 1, psoas 1, and in the remaining 8 cases it was not stated whether metastases were found or not.

Symptoms.—Though usually few in number, the symptoms of primary carcinoma of the pancreas are of such a character as to be of little diagnostic value. Ordinarily the first symptom noticed by the patient is pain. This is located in the upper part of the abdomen, many times localized to the upper umbilical region, and again it may be localized either in the right or left

hypochondrium. The pain is paroxysmal in almost every case and often cutting in character, or it may be lancinating. Again, it may be only a dull ache. Sometimes the pain resembles that of biliary colic so closely that the two diseases may be confused. The next most prominent symptom is a progressive emaciation, being found in varying degrees in every case. In some cases the emaciation is very rapid, while in others it is only slowly progressive. Though a symptom secondary to the organ diseased, jaundice is found in many cases. The reason for this is obvious, since most of the primary carcinomas of the pancreas arise in the head and so either by involvement of the common duct or from pressure from without, the lumen of the common duct is diminished and so the outflow of bile is hindered. This leads to a dilation of the gallbladder, later to an enlargement of the liver, and finally to general jaundice. Hand-in-hand with jaundice, one usually finds intestinal disturbances such as flatulency and diarrhea with clay-colored stools, especially in the later stages. While diarrhea is the more common, constipation may become a disturbing symptom. I found it reported as such in 9 of my series of 50.

From the nearness of the affected organ to the stomach, symptoms on the part of that organ are common, such as nausea, vomiting, gaseous eructations and other symptoms of "dyspepsia," becoming so prominent in some cases that the real disease is overlooked and the patients are treated for chronic gastritis. From pressure upon the portal vein by secondaries in the portal fissure or by the primary tumor itself, ascites may result. From pressure on the vena cava, edema of the lower extremities may be brought about. I found this symptom reported in 4 of the 50 cases. In one case reported by Vance⁸ chylous ascites was noted. In his case this symptom became so distressing that he was compelled to tap the patient's abdomen three times before death. No postmortem notes were added to the report, but in all probabilities the receptaculum chyli contained secondaries or was pressed upon by the primary tumor mass.

Petechial spots are sometimes present. I found them reported in 3 of the 50 cases. They were noticed over the abdomen and chest and in the axilla; in White's⁹ case they were found over all the flexor surfaces. Thrombosis of the saphenous vein alone may occur and be followed by its train of symptoms. In a case reported by Cane,¹⁰ this condition had been present. Later the patient developed a hemiplegia and still later an aphasia. Complete obstruction of the intestine may occur, but it is not common. I found it reported in 2 cases. One was reported by Flexner,¹¹ and in his case it was suspected before death that the cause of the obstruction was a carcinoma of the pancreas. The other case was reported by Beck,¹² and in his case malignant disease of the sigmoid and later the ascending colon was supposed to have caused the obstruction.

In one case, reported by Masters,¹³ the onset and course of the disease for some time was very similar to an acute infection. When first seen, the patient had an elevation of temperature and rapid pulse following a chill, acute headache, bilious vomiting, constipation, coated tongue, and general malaise. These symptoms continued for eight days and then subsided. Ten days

⁷ Suckling, *London Lancet*, 1889, I, 127.

later these same symptoms returned for six days. At the time of the second attack, the patient had lost weight rapidly. Later, he complained of pain in the splenic region and the spleen became much enlarged. Jaundice was never present, though the skin "looked muddy." After a little time the patient developed an irritable cough with little expectoration. Examination of the lungs at that time showed nothing abnormal. At times the skin of the patient would be bathed in a profuse perspiration. He died soon after, and at autopsy a carcinoma of the head of the pancreas about the size of a hickory nut was found.

Physical examination in primary carcinoma of the pancreas usually reveals little. If the gallbladder is distended and the liver enlarged, these may be made out. An appreciable tumor in the region of the pancreas can be felt in some cases. I found it reported in 16 of the 50 cases, while in 2 cases, even under chloroform-anesthesia, no tumor could be felt. Examination of the stools shows a large amount of undigested fat. I found its presence reported in 6 cases of the 50, while 6 others, which were examined for it, showed no fat. Of the 6 in which fat was found in the stools, at autopsy, a duodenal ulcer complicating the carcinoma of the pancreas was found in 1 case, and compression of the pancreatic duct was demonstrated in the other 5. Of the 6 in which fat was looked for with negative results, 1 was a case of diffuse carcinoma, 2 were located in the head and the location of the others was not cited.

One is struck by the fact that the examination of urine in so many cases shows no sugar. From the involvement of the pancreas by carcinoma, you would expect to find diabetes present, but as Hansemann pointed out, the most probable reason we do not find it present oftener is that the course of the disease is too short for diabetes to develop. I found sugar in the urine reported in but 6 cases of the 50.

From these symptoms it can be seen how difficult it becomes to diagnose a carcinoma of the pancreas.

I now wish to present 4 new cases which have come under the observation of the Pathological Laboratory of the University of Michigan, and which are here reported for the first time.

CASE 1 came under the care of Dr. Schcepffe, of Sandusky, Ohio; male, painter, age 50, previous history negative. The patient had never been sick until April, 1899, when he was suddenly taken ill with severe pains in the region of the umbilicus. A diagnosis of "lead colic" was made then, and he was treated for that. He did not improve, but began to emaciate. The pain became severe and constant in the right side, and paroxysmal in the region of the umbilicus. The abdomen became retracted, and the muscles so rigid that no examination of this region was possible. Later, jaundice developed, the liver became enlarged, and several nodules could be felt on the anterior surface of the liver, moving with respiration and showing umbilication. For a short time previous to the appearance of the jaundice the stools were offensive, clay-colored and contained particles of undigested food. His appetite remained good. The only symptom on the part of stomach was vomiting, which occurred 3 times, twice, undoubtedly, as the result of spoiled food, and once from no apparent cause.

At autopsy, the body was extremely emaciated and deeply jaundiced. A tumor was found involving the whole of the pancreas, and pressing upon the stomach and gallbladder. The liver was enlarged, icteric, and contained a large number of secondaries. The gallbladder was distended with bile, but contained no secondaries. The stomach was greatly dilated, reaching almost to the pubes. It contained no secondaries. On the surface of the left lung were a few small nodules. None were found on the heart. The entire pancreas, with parts of the liver containing secondaries, were sent to the laboratory for examination.

Sections taken from the main tumor mass show a framework of connective tissue, embedded in which are nests of cells of varying shapes and sizes, and possessing no intercellular substance.

The connective tissue which goes to make up this framework is, in most places, comparatively rich in nuclei, and the intercellular substance stains pinkish yellow with Van Gieson's stain. In some places the nuclei are few, and the intercellular becomes more marked, is glassy and stains bright rose red with Van Gieson's stain.

The cells which form these nests are closely packed together, and are irregular in shape. These cells contain nuclei which are round or oval, sometimes lobulated in shape, and are surrounded by an arrow ring of finely granular protoplasm. Most of cells are mononuclear, but some are polynuclear. The nuclei stain with varying intensities, some faintly, others darkly.

Those nuclei which stain the fainter when examined under an oil immersion $\frac{1}{2}$ inch are seen to be made of a coarse reticulum or linin network and a finely granular substance filling its meshes. On this network at varying intervals, the ids are seen. These ids are round or oval, and are of varying sizes. Some are only fine granules, others are much larger, and others 10 or 12 times as large as the smallest ones, and staining much more deeply. These, I take it, are the tumor cells in the resting stage.

There are areas where most of the nuclei stain deeply, and here one finds cells in all stages of cell division, but the division is not normal, for in some of the cells are found 2, 3, or 4 spindles on which the long chromatic filaments are seen. A striking peculiarity is seen in these nuclei which contain more than one spindle. When compared to those nuclei containing only one spindle, one sees that chromatin filaments in the nuclei with more than one spindle are just as many and just as large as those of the nuclei of only one spindle.

Then one sees other cells with nuclei which are just rearranging their chromatin filaments for the resting stage, and one sees a great irregularity in size and shape of their chromatin ids. Some are round or oval, others elongated, others spindle or pear-shaped, and others are clubs-shaped.

In the protoplasm of many cells, one finds vacuoles which in some are filled with a finely granular material not staining at all, and again the protoplasm of some cells shows a stringy or finely granular change in a varying amount, and these cells, when stained with Delafield's hematoxylin, give the reaction for mucin.

While most of the nests show a solid formation, in the center of some a space is seen in which the cells have been replaced by a granular matter staining brownish-yellow with Van Gieson's stain, and in which one may see little blue granules—the remains of the chromatin.

While the tumor, on the whole, shows it to be made of these solid cell nests, in some areas, it takes on a distinctly tubular type. Here, in these places, the connective-tissue framework is small in amount, being, as a rule, only 2, 3 or 4 cells in thickness. This connective tissue contains a moderate number of nuclei and relatively large amount of intercellular substance staining pinkish with Van Gieson's stain. The cells which lie between these trabecula of connective tissue are cuboidal in shape, and have no basement membrane. The number of cells in thickness in these spaces varies from 2 to 6 or 7. In all respects as to their finer anatomy they resemble the cells found in the solid cell nests, and described above.

The tumor receives its blood-supply from vessels which run in the definite connective tissue stroma, and it has involved some of them by secondary growth, and since these show some striking points, I wish next to describe them. Some of the vessels have their lumen completely obliterated by growth into it of tumor cells, and others have their lumen partially or wholly closed by laminated thrombi, and when these are examined, one finds places where 2, 4, or 6 cells are seen which are entirely surrounded by fibrin and blood-cells of the thrombus. In some vessels it is easily seen how these cells become loosened and lie out in the thrombus. If one follows back along the vessel wall one sees a place where the wall has been involved by the tumor from without. First, there has been an invasion of the adventitia. From this coat the tumor cells have proceeded along the lymph spaces into the media and intima. Then points are

seen where the tumor cells have broken through the intima and have grown into the lumen. It is in these vessels that the laminated thrombi are found in which these loosened cells are noted. The cells found loosened in this wall possess all the characteristics of those found in the primary mass.

Along with the growth into the bloodvessels, the nerve-trunks have become involved. The amount of the involvement varies in nerves which show only 2 or 3 cells under their perineurium to those nerves which have become wholly replaced by tumor cells. In some of the nerves the course of the involvement can be seen. The cells are first seen as a small nest of 2 or 3 cells growing in the lymph spaces under the epineurium. From here they grow along lymph spaces till they are seen under the endoneurium. From here one can trace them along as they form a wedge between the nerve fibers, and by their proliferation causing the axis cylinder and medullary substance to disappear. In some places remains of the medullary substance can be seen as fine granular matter remaining inside the neurolemma, and staining yellow with Van Gieson's stain. Then, again, one sees places where the neurolemma with its nuclei still remains, but the space formerly occupied by the axis cylinder and medullary substance has become greatly distended. In some of these distended spaces one may find the same granular material mentioned above, but in many carcinoma cells are found filling up the space. In some the carcinoma cells do not completely fill the space, and are surrounded by this same granular matter.

All the ducts of the pancreas are greatly dilated and cystic. The epithelium lining them has undergone a mucous degeneration. In many places the epithelium has become hypertrophic. Sections taken from the nodules in the liver show them to be the same in structure as the primary growth in the pancreas. The liver-cells that remain show a brown atrophy. Sections taken through the duodenal wall show that the tumor was confined almost entirely to the tissues outside the muscular layer, but in one or two places small metastases were found in the muscular coat. All the lymph-glands in the neighborhood of the pancreas show secondary new growth in varying amounts.

From this it is seen that we have a primary adenocarcinoma of the pancreas arising from the acinous cells, with secondaries in the liver, wall of the duodenum, the neighboring lymph-glands, nerves, and bloodvessels.

CASE 2.—This was a specimen of pancreas and stomach, brought to the laboratory by Dr. Kingsley. Little clinical history of the patient was given, except that the patient suffered from chronic gastritis, and was treated for such. No malignancy had been suspected. At autopsy a mass the size of a half coconut was found replacing the pancreas and adherent to the stomach-wall.

Sections taken from the tumor mass show a framework of connective tissue, relatively rich in nuclei, in the meshes of which one finds nests of round or oval or irregularly shaped cells, closely packed together with no intercellular substance. Most of the cells forming these nests have only a narrow ring of protoplasm surrounding one nucleus, many of them, however, having been polynuclear, some of them being giant cells. Regarding the more minute anatomy of the cells which form the cell nests, it is hard to judge, for the tumor was not placed in any fixing fluid for 2 or 3 days after the autopsy, and so the cells had lost some of their finer points. As far as I am able to judge, these cells resemble in general those of the previously described tumor in their finer anatomy, with the exceptions that the nuclei show a greater tendency to become vacuolated, and that the cells themselves are larger in size. There had been secondary infiltration of the muscular coat of the stomach. My diagnosis, then, is a primary adenocarcinoma of the pancreas, arising from the acinous cells, with secondary infiltration of the stomach-wall.

CASE 3.—This was a case observed by Dr. Dock, and I am indebted to him for the clinical and autopsy data. Female, age 73, first seen December 4, 1895. At that time she had been suffering from jaundice for 3 weeks and emaciation for several months. For 3 days previous she had been vomiting blood. Examination showed marked jaundice and advanced emaciation. The abdomen was flat, and in the

epigastrium, just above the umbilicus, a hard, smooth, oval mass about the size of a goose egg was found. In the right flank, continuous above with the liver-dulness, a smooth, semi-elastic pear-shaped tumor was outlined. A diagnosis was made at that time of carcinoma of the pancreas. On the 7th, hemorrhages into the skin were noticed. At this time she complained of pain in the left groin and along the sciatic nerve, and numbness of the left leg. At the same time swelling of the left cheek was noticed. There had been no hemorrhages from the stomach, but small ones had occurred from the anus and the mouth. The patient died soon after and came to autopsy January 10, 1896.

Examination of the epigastric tumor showed that it had decreased in size, and that it had become more difficult to palpate than the tumor in the side. The skin and serous membranes were deeply jaundiced and contained many ecchymoses. A small amount of bloody fluid was found in the abdomen. In the head of the pancreas, a tumor, about the size of a hen's egg, was found. The tumor was conical in shape, nodular in outline, and alveolar in structure. The remainder of the pancreas was small and fatty. The pancreatic duct would not permit the passage of a firm probe, and was dilated to the middle of the tumor. The common and hepatic ducts were $2\frac{1}{2}$ cm. in diameter, and the cystic duct was 7 mm. in diameter. The gallbladder was distended to about the size of a goose egg. The liver was dark green in color with pale yellow areas. The bile ducts were dilated and filled with bile. There were a few small cavities throughout the liver, and these were filled with clear fluid. The stomach was negative. No hemorrhages into the mucous membrane of the stomach were seen. Hemorrhages were found in the pelvis and beneath the serosa of the descending colon. Sections taken from those parts, which are nearest normal, show an increase of the connective tissue and a cloudy swelling both of the acinous cells and the epithelial cells of the areas of Langerhans. Sections were taken from the tumor mass, and in these sections there is a slight increase of the connective tissue and a cloudy swelling of the acinous cells. The areas of Langerhans show some marked changes. Some of them show a slight enlargement. Their epithelial cells are enlarged, and their nuclei very deeply, and in some of these areas one can see the lymph clefts between the masses of cells, and these show a beginning dilation. Other areas of Langerhans are seen in which the solid arrangement is lost entirely, and the cells have become arranged in anastomosing rods of 1 or 2 cells in thickness, and in these areas the lymph clefts have become greatly dilated. The cells which form these rods are large cuboidal-shaped cells with a relatively large amount of finely granular protoplasm surrounding a round or oval-shaped, deeply staining nucleus. In other areas of Langerhans, the rods are thicker and the lymph spaces still more dilated. The rods in these areas are made of cells, 4 or 5 in thickness, or even more in some places. In some parts of such areas one sees that the spaces found in them are not lined by the endothelium, but by the epithelial cells themselves, and in some of these cyst spaces one finds a granular debris in which desquamated cells and a few leukocytes are seen.

When the large trabeculae of connective tissue are examined, one sees nests of cells growing in the lymph spaces, having no intercellular substance, and limited by no basement membrane. The cells are irregular in shape and have a relatively large amount of protoplasm surrounding a round or oval nucleus which stains deeply. These nuclei show a reticulum on which the chromatin is arranged at varying intervals. These is vary in size, shape, and staining capacity, and in some of the nuclei atypical cell-division figures could be seen. In the larger of the cell nests one sees that the cells of the central portion have undergone a simple necrosis.

The pancreatic ducts are greatly dilated and cystic. The cells lining them have undergone a mucous degeneration, and the lumen of these ducts is filled with a stringy and, in some places, granular matter.

From these sections I diagnosed the tumor as a cyst-adenocarcinoma of the pancreas arising from the areas of Langerhans.

CASE 4.—This was a case which came under the observa-

tion of Dr. Nicola, then of Battle Creek, Mich., specimens of the pancreas having been sent to the laboratory for examination. Little clinical and no autopsy data were sent, except that it was thought to be a case of chronic gastritis during life, no malignancy having been suspected.

Sections taken from those parts which are apparently normal show that the connective tissue is increased to a slight extent, and that the acinous cells and the epithelial cells present cloudy swelling. Even here, in some of the areas of Langerhans, one sees occasionally a small dilated lymph space between rods of cells.

As one leaves these portions of the pancreas and examines sections taken from regions nearer the tumor mass, changes are seen in the areas of Langerhans. They begin to be enlarged, and they lose their solid appearance. The cells become arranged in an anastomosing network of rods, 1, 2, or 3 cells in thickness. The meshes between the rods are lined by endothelium, and are dilated. Then, there are other areas where the rod arrangement is not retained, but these cysts are seen to be lined by a mass of the epithelial cells, 5, 6, or even 8 or 9 cells thick, and no endothelium can be seen. In the cyst space, a granular matter is found, and embedded in it are desquamated cells. The nuclei of the cells, which so line the spaces, show an irregular arrangement of their chromatin ids, and some are vacuolated, and some irregular division figures.

In the lymph spaces of the connective tissue trabeculae of the pancreas, nests of cells are seen which are growing with no intercellular substance. These cells resemble those described above. The pancreatic ducts are dilated and cystic, and their epithelial lining shows mucous degeneration.

The microscopic findings, then, present the same picture as that found in the sections taken from specimens of Case 3, with the exception that the conditions found are more pronounced and one is enabled to see more division figures in the extremely cystic areas of Langerhans which are undergoing a malignant change. So that my diagnosis in this case would be a primary cyst-adenocarcinoma of the pancreas arising from the areas of Langerhans.

In conclusion I wish to emphasize some points more fully. In Case 1, I would point out the probable cause of the intense pain in the involvement of the nerves by the carcinoma. Another point I would emphasize is the finding of free carcinoma-cells out in the thrombus. From this it is easy to see how these cells might be set free in the blood-stream and lodge elsewhere and form secondaries. In Case 2, I would emphasize the difficulty of making a diagnosis of carcinoma of the pancreas, for this case was diagnosed clinically as a case of chronic gastritis and treated for such, no malignancy having been suspected. In Cases 3 and 4, I would point out again their origin. In these cases we can trace the development of the carcinoma from those areas of Langerhans in which the epithelial cells are hypertrophic, through those stages in which the areas of Langerhans are hyperplastic, and others are adenomatous, to those which show cyst-adenocarcinoma.

ANGINA LUDOVICI.¹

By G. G. ROSS, M.D.,
of Philadelphia.

Assistant Surgeon German Hospital, Philadelphia.

LUDWIG's angina, or phlegmonous cellulitis of the floor of the mouth, is a comparatively rare affection. It is a disease which is so rapid in its development and is attended by symptoms so distressing in character and accompanied by such a high rate of mortality that any addition to the literature extant upon the subject may be of interest.

Ludwig, of Stuttgart, in 1836 was the first to describe the disease in detail, hence the name.

The disease is an infection of the thick layer of loose connective tissue which fills in the space between the symphysis of the jaw and the muscles of the floor of the mouth. This tissue is rich in lymphatics and bloodvessels, and contains the ducts of the sublingual and submaxillary glands.

The disease may be either primary or secondary.

Primary infection may arise from wounds or ulcerations of the floor of the mouth and carious teeth; retarded development of the third molar, or so-called wisdom tooth, is an especially fruitful source of the trouble. Frequently a third molar will develop in the angle of a jaw already filled with teeth, causing pressure necrosis of the tooth, and the portion of alveolar process of the jaw forming its bed, thus giving rise to an abscess and a subsequent infection.

The secondary infections arise in conjunction with those infectious diseases which are accompanied by manifestations in the mouth, *e. g.*, diphtheria, scarlet fever, tonsillitis, etc.

An interesting discussion has arisen as to the differentiation of the acute infectious diseases of the larynx, pharynx, and floor of the mouth. Semon² claims that "the various forms of acute septic inflammation of the throat and neck, hitherto considered as so many essentially different diseases, are in reality pathologically identical, that they merely represent degrees varying in virulence of one and the same process, that the question of their primary localization and subsequent development depends in all probability upon accidental breaches of the protecting surface through which the pathogenic microorganism, which causes the subsequent events, finds an entrance, and that it is absolutely impossible to draw, at any point, a definite line of demar-

¹ Read, November 5, before the Philadelphia Academy of Surgery.
² Royal Medical and Chirurgical Society, London, 1895, vol. lxxviii, 181 to 233.

cation between the purely local and the more complicated, or between the edematous and the suppurative forms."

He reports 14 cases, all of which were of the secondary type of infection. It would seem clear from his cases to consider the acute septic infection of the larynx and pharynx as one and the same disease, and, so far as the character of the invading microorganisms is concerned, the primary may be included.

However, in true angina ludovici, the course is different and the infection essentially primary. The point of entrance is in the mouth proper, and the disease manifests primarily in the floor of the mouth and secondarily in the pharynx and larynx.

The pathology, so far as known, is very similar, if not identical, with that of erysipelas. The organisms which have been discovered from the researches of modern investigators are the streptococcus and the staphylococcus. It has been suggested that there is some organism which is especially virulent and active in this disease, but as yet it has not been discovered.

G. Leterier³ has collected 31 cases with 13 recoveries. This series includes cases collected from old literature, and the mortality is therefore higher than at present. Early recognition of the disease and prompt surgical interference will, in all probability, still further reduce the death-rate. Spontaneous cure by rupture of the abscess into the mouth may occur, but the majority will terminate fatally unless operation is instituted.

The symptoms are marked from the onset of the disease. They develop very rapidly and are of the greatest severity. Frequently in a few hours after the earliest manifestation of the disease a hard swelling will be found between the arch of the lower jaw and the hyoid bone. The swelling spreads rapidly, soon involving the neck and face in a hard, dark red, brawny induration. Respiration is soon impeded by involvement of the deep connective tissue of the neck. The pharynx and larynx become involved, and attacks of acute dyspnea with cyanosis supervene. The swelling may spread downward to the anterior mediastinum, and on to the chest-wall. Inspection of the mouth, although unsatisfactory due to fixation of the jaw, will disclose the sublingual tissue to be so edematous as to push the tongue against the roof of the mouth. In the early stage the swelling is unilateral, but soon both sides become involved and deglutition becomes difficult or impossible. Supervening the local condition a marked general sepsis occurs.

CASE 1.—Dr. W. S., while studying in Berlin, had an acute infection of the submaxillary region arising from a necrotic and undeveloped wisdom tooth. The inflammation developed rapidly and in twelve hours from the onset of the attack the symptoms were so marked that operation was demanded without further delay. The wisdom tooth being pried away from the last molar, fetid gas and pus escaped; the inflammatory mass in the submaxillary region was then incised. The symptoms rapidly subsided, only to recur a few weeks later, when he was again operated upon and the offending tooth chiseled out.

CASE 2.—Carl S., Austrian, aged 20. Family history good. Personal history excellent. Gastric fever at the age of 6; no venereal trouble. Uses alcohol moderately and tobacco in excess.

He worked his way to this country, and attributes his bad teeth to neglect during the voyage. He is a printer by trade, but had been a farmhand for the three months of his residence in America.

Had had toothache for four days prior to his admission to the German Hospital, September 29, 1900, about 8 P.M. At

the time of admission there was some swelling and induration in the left submaxillary region, red and angry looking, very painful to touch, and interfering with the motions of the jaw. Respiration 24, temperature 102°, pulse 86, full and bounding. Three hours after admission he awoke with a marked dyspnea and cyanosis, which partially subsided only to recur again with increased severity. The attacks of dyspnea seemed to come in periods and were relieved by violent voluntary inspiration. He would grasp the porch railing, extend his neck forcibly and thus enable himself to inspire enough oxygen to last for a few minutes. The house surgeon prepared for an immediate tracheotomy, which, however, was deferred from time to time upon the amelioration of the attacks. By 12.30 A.M. the induration and swelling had extended from the angle of the jaw on the left side to that of the right and down the neck to the clavicles. The hyoid bone and Pomum adami could not be made out. The swelling was hard, very painful, dark red, and brawny in character, not unlike that of erysipelas.

The chin was held well advanced and rigid. The jaws were separated about half an inch, and between the teeth the under surface of the tongue could be seen; the latter being pushed upward to the hard palate by the edematous sublingual tissues. The jaws were forced apart, disclosing a general edema of the anterior pillars of the fauces, buccal mucous membrane and the sublingual tissues; the last two molars were carious and an undeveloped wisdom tooth was present.

An incision was made into the edematous sublingual tissue on both sides of the frenum. A considerable amount of bloody serum escaped and in a few minutes his respiration became less labored. Icebags were applied and the patient returned to bed; he slept for some hours. The temperature reached 104° and the pulse 118 by 5 P.M., September 30.

On October 1 the swelling had increased until it extended upward upon the face as far as the zygomatic arches and down upon the chest-wall to midsternum. Fluctuation was now unmistakable for the first time just below the symphysis of the jaw.

A few whiffs of chloroform were administered and the abscess opened by an incision which went through the muscles forming the floor of the mouth. The abscess cavity extended around the entire under side of the jaw from angle to angle. The pus which escaped was extremely fetid. As this stage of the proceeding was reached, the patient ceased breathing, necessitating an immediate tracheotomy, and this in a neck with obliterated landmarks. Respiration being reestablished, the operation was completed by the removal of the offending teeth. A mallet and chisel were necessary for the extraction of the wisdom tooth. The patient reacted promptly. By the fourth day after operation 2 patches of impaired resonance could be made out, one in the right lung in the midaxillary line, the other at the left base. There was, however, no evidence of a frank pneumonia.

On the fifth day a secondary abscess on the right side, extending from the submaxillary region to the zygomatic arch, was opened which allowed a quantity of fetid pus to escape. Prior to the evacuation of this secondary collection deglutition had been impossible and rectal alimentation had been resorted to. In a few hours he was able to swallow liquids freely. The tracheal tube was removed in 36 hours. The convalescence was progressive despite an attack of bronchitis. The after-treatment consisted of iron, quinin and forced nourishment.

As a result of the inflammation of the larynx, aphonia has resulted. The condition of his larynx (as reported by the laryngologist) is as follows: "The larynx shows evidences of an attack of perichondritis. The vocal cords are hidden by the greatly swollen and thickened ventricular bands. The arytenoid cartilages are also obscured by swollen mucous membrane which also involves the interarytenoid space. There appears to be no paralysis of the laryngeal muscles, but their normal action in phonation is prevented by the greatly thickened condition about them. Directly in the center of the laryngeal opening a passage sufficient for respiration leads down to the trachea, between the swollen ventricular bands."

The pathologic report states the bacteriologic findings as follows:

³ Du l'hlegmon sublinguel dit Angina. *Thèse*, Paris, 1893.

Examination was made of the patient's blood and of pus from the wound, both taken October 2, 1900. The blood was removed from the median cephalic vein by means of an aseptic hypodermic needle after aseptic incision of the skin overlying the vein. A moderate quantity of blood was introduced into 6 bouillon tubes and 4 agar tubes. These were examined on several occasions, but all remained sterile at the end of 10 days. From the pus cover-slip preparations were made and several bouillon tubes and agar tubes were inoculated. The cover-slip preparations revealed staphylococci and streptococci. The inoculated tubes also revealed streptococci and staphylococci; the latter by further culture methods proved to be *Staphylococcus pyogenes aureus*. On October 6 another examination was made of the pus from the wound, cover-slip preparations and inoculations again being utilized. These again revealed *Staphylococcus pyogenes aureus* and *Streptococcus pyogenes*. The latter grew both in short chains as well as in long chains, many of them being excessively long.

Blood-count: Hemoglobin, 63%; erythrocytes, 4,630,000; leukocytes, 9,800.

There is another valuable lesson to be learned from Case 2. The character and severity of the symptoms and the destructive tendency of the inflammation lead to the isolation of the patient. The clinical manifestations and pathologic finds so nearly resemble erysipelas that in an active surgical hospital these cases should be isolated.

About 6 weeks after the operation and 2 weeks after reporting Case No. 2, the patient developed a slowly progressive dyspnea and died suddenly on November 21, 1900. The postmortem showed a deep ulceration of the larynx, almost totally destroying the vocal cords. The opening in the larynx was free enough to preclude respiratory failure. The kidneys showed some nephritis; the other organs appeared normal.

A CASE OF DECIDUOMA MALIGNUM.

By JOSEPH McFARLAND, M.D.,

Professor of Pathology in the Medico-Chirurgical College, Philadelphia.

THE following case, although the true diagnosis was only recently made, was observed a number of years ago, and was reported in the *Medical News* for December 8, 1894, as a "Large round-cell sarcoma of the uterus." The morbid specimens only are known to me, the case having occurred in the Kensington Hospital for Women, in charge of Dr. Charles P. Noble, to whom I am indebted for the following clinical memoranda:

Mrs. K., aged 30 years, white, married, mother of 2 children, the youngest of whom is 30 months old. Between the births of the children she had one miscarriage. In September, 1892, when the youngest child was about 21 months old, menstruation became profuse and continuous so that by June, 1893, she was very feeble and anemic, and consulted Dr. Noble, complaining only of the hemorrhage. An examination was made and the uterus found to be much enlarged and discharging a foul-smelling bloody fluid. A clinical diagnosis of sloughing fibroid or cancer of the fundus was made, and on June 23 the organ was curetted, and a large quantity of necrotic tissue removed. The amount of this material led Dr. Noble to believe that the case was one of sarcoma.

A fragment of the tissue was sent to me as pathologist of the hospital, and was subjected to microscopic study with the result that nothing of interest could be determined, as the fragment consisted exclusively of necrotic tissue whose elements were no longer recognizable. I

reported upon the findings and hazarded the opinion that the case was one of necrotic submucous fibroid.

The anxiety which Dr. Noble felt about the case led him to operate more radically without awaiting the result of my examination, and on June 28, 1893, a vaginal hysterectomy was performed. The patient made a good recovery from the operation and remained well until November, 1893, then again called upon Dr. Noble, who found her ill in bed, with profoundly embarrassed respiration, and aspirated about a pint of blood-stained serum from the chest, slightly relieving the symptoms. Several small tumors were pointed out at this time, one under the skin of the breast, another under the skin of the loin, and a third under the skin of the thigh.

When seen later in her illness, the patient was breathing 80 times per minute and the pulse was so rapid that it could scarcely be counted. Respiratory sounds were absent over the front of the chest, and there was evidence of pulmonary consolidation on the

right side posteriorly. The patient died December, 1893.

The extirpated uterus was sent to me for examination. It was enlarged to nearly the size of a small fist, the shape was pyriform, the surface smooth, the cervix normal. I opened the organ by a longitudinal incision on the anterior surface and found a dark-colored, ragged tumor projecting into the cavity of the organ from the posterior superior wall. I did not receive the specimen in the fresh condition, but hardened in Müller's fluid, which prevents me from saying whether the tumor was originally soft or firm. The preservative had made it hard and firm and the appearance was so completely suggestive of a submucous fibroid ulcerated and damaged by the curet, that I wrote to Dr. Noble that the microscopic examination confirmed my original diagnosis and that the tumor was a necrotic fibroid. Some large sections of the tumor, extending entirely through it and through the uterine wall, were made, and a very careful examination made of the cervix. When these sections were examined I found the cervix normal, the uterine wall itself normal, but the supposed necrotic fibroid consist-

ing of a hemorrhagic and necrotic matrix rather irregularly penetrated by areas of peculiar cells irregular in size and of very obscure histogenesis. I was much interested in this discovery, but failed at the time to determine its significance, and the specimens were laid away. After the death of the patient Dr. Noble wrote to me about her and the subsequent events in the course of the case and I studied the sections again very carefully, and on December 8, 1894, published my opinions in the *Medical News*.

The case, therefore, has gone on record as a "Sarcoma (Endothelium?) of the Uterus." I doubt whether anyone would be able from the published description to determine that the case is one of deciduoma, though upon reading them over I find them so accurate that I need not repeat them.

The slides were again laid away for some years and might have remained untouched forever if in rearranging my collection I had not unexpectedly unearthed them. I remembered the peculiar tumor well, but had lost the mental picture of the histologic lesions. Upon again glancing over the slides the true nature of the growth, which in the meantime has become well known, became at once apparent and I find it perfectly corresponding in detail to the numerous cases that have been published and figured since I wrote my original description 6 years ago. The microscopic appearances are well shown in the accompanying illustration.

COMPOSITE TERATOMA OF THE OVARY; PATHOLOGIC REPORT.

By EDGAR ALLEN JONES, A.B., M.D.,

of Birmingham, Ala.

Instructor in Pathology, Birmingham Medical College.

THE following case, which I have the privilege of reporting through the courtesy of Dr. W. E. B. Davis, who performed the operation, is of unusual interest for several reasons which become evident upon a recital of the history of the case, together with the pathologic findings:

Mrs. N., aged 34, married. Mother of three children; had always menstruated regularly (except when pregnant or nursing child). She noticed a growth in the left side (iliac region) 2 years ago; menstruated in January before the growth was noticed, then missed until March, at which time she bled very freely for 2 weeks; missed periods until following October with no untoward symptoms, except an attack of "colic" in August; after October she menstruated regularly until following January, missing from then to October 24, 1899, when she was delivered of a child at full term. She has not menstruated since. After the birth of this child the tumor developed quite rapidly, and on May 7, 1900, she was operated upon at Dr. Davis' private hospital. The diagnosis of an old ectopic pregnancy had been made. The tumor filled up the left side of the pelvis and was attached to the uterus by a large pedicle. The tumor was about the size of an adult head, and was firm in consistency.

Pathologic Description.—Examination reveals a large rounded ovoid mass (about size of adult head), covered by a moderately thin, fibrous capsule. The capsule is continuous on one side with the tumor mass. The weight of the whole tumor is 2,850 grams. Within the capsule are observed numerous sacs of variable size, which are rounded in contour, and are filled with a semifluid, gelatinoalbuminoid tissue. Lying in one side of the mass is part of a fetus. The fetus has the appearance of having reached the sixth or seventh month of fetal development. There are numerous bones of a fetus lying free in the capsule. The upper part of the fetus is embedded in the solid portion of the tumor,

and this part of the fetus is so intimately combined with the tumor that no sharp line of demarcation can be made out.—one tissue gradually passing over into the other. There are numerous nodular and teat like elevations in the tumor. Some of these are covered by smooth skin (?), others by skin (?) provided with fine, silky, brownish hair. Incision of these frequently reveals a whitish, cheesy substance, which very closely resembles sebaceous secretion. The soft parts of the fetus are macerated and quite soft. The bones, such as vertebrae, ribs, tibiae, and metatarsal, are exposed in many places. There are two well-developed scapulae,—right and left, and to the left is attached some slight semblance of an extremity. Lying in a mass of muscular tissue to the left of the vertebral column is a long piece of bone somewhat resembling a humerus. Attached to the lower end and left side of the vertebral column by means of a flattened piece of bone, is an almost perfect lower extremity. The femur is entirely covered by muscle, but the tibia is exposed at its lower end. Some of the phalanges are missing, but the foot is fairly well formed. Careful dissection of the upper part of the fetus fails to reveal any bones attached to the vertebral column. There are two pieces of jaw bone (inferior maxillae) lying in the mass of tissue at this place. They are well shaped, and dissection of one shows rudimentary teeth, and a piece of nerve. The laminae of the vertebrae have not united, so that the spinal canal is not complete, and the spinal cord is seen lying in this position, with nerves arising regularly from each side. The bones lying free within the capsule are: Two parietal, 1 occipital, 2 pieces of frontal, abnormally united, several well-formed ribs, and 5 or 6 long bones (of extremities). Parts of the lung, liver, the stomach, and about 60 cm. of the intestine are preserved.

Microscopic Examination.—Microscopic examination of sections of tissue, selected from all portions of the tumor, shows a very complex histologic structure. Some portions of the tumor are composed of simple, fully developed, adipose tissue, enclosing occasional bands of unstriated muscular tissue, the whole surrounded by fully developed skin. The skin contains sebaceous and sweat glands, and hair follicles, with hairs in position. The sebaceous glands are larger than those found in normal skin. Sections from other parts of the growth show true myxomatous tissue, still others, cartilage, and early stages of osseous development. Sections from the walls of cysts show the inner surface of some to be lined by true skin; the epithelial layers lie internally—line the cyst cavity—the papillary portions lying externally. Sebaceous and sweat glands occur in these sections, and frequently they may be seen opening into the cysts. Other cysts are lined by a simple layer of low cubical epithelium, either in uniform arrangement or thrown into folds or villi, similar to the formations found in uncomplicated cystic papillomatous adenoma of the ovary. The lining of other cysts is made up in some parts of flat or squamous epithelium, in other parts by columnar or cubical epithelium of the glandular type, and frequently one kind of epithelium passes over into the other.

Anatomic Diagnosis.—Composite teratoma, combined with cystic adenoma of the ovary.

The most interesting feature of this case is the fact that the fetus was so large, and, on casual observation, so well formed, that it could be easily mistaken for an ectopic gestation which had ruptured into the cavity of a preexisting ovarian cystoma. As has been stated above, the diagnosis of ectopic pregnancy had been made from the history of the case.

As to the origin of teratomas, many investigators give many opinions. The origin of the simple epidermoid cysts, and the true dermoids (Orth), is probably correctly explained by the theory that there is an infolding of the skin during fetal development, with ultimate separation of the thus formed cyst from the surface of the body. To account for the origin of the more complex dermoids—the simple and the complex teratomas (Orth)—is not so easy. The facts that these growths occur in children, and in young women (virgins), serves to disprove the theory of ovarian preg-

nancy. The theory of the development of an ovum without impregnation — parthenogenesis — has some supporters. Cohnheim's theory of embryonal remnants, capable of producing different kinds of growths (dependent upon the type of the cell), is reasonable, but it is strange why so many of these growths occur in the ovary. The theory which has the greatest support, by the greatest number of observers, is that of fetal inclusion; i. e., the inclusion within the body of a developing fetus, the remains of an imperfectly developed twin. This, too, is subject to the criticism applied to Cohnheim's theory, but it seems more plausible than any of the others. Finally, it must be admitted that the pathogenesis of the teratomata is very obscure.

I wish to thank Dr. H. T. Brooks, of the Post-Graduate Hospital, New York City, for valuable help in the examination of this specimen.

DERMATOMYCOSIS TONSURANS.

By W. B. REID, M.D.,
of Rome, N. Y.,

Surgeon on the Staff of the Rome Hospital; Member of the Rome Medical Society; the Oneida County Medical Society; Non-Resident Member of the Syracuse Academy of Medicine, and the New York State Medical Association.

THE case here reported, for the purpose of record, is one of dermatomycosis tonsurans. It is of interest first, because of the rare source of the infection; secondly, because of the still more rare form and manner of the attack.

There are three principal varieties of ringworm included under the term *tinea trichophytinea* or *trichophytosis*, but all arise from the one vegetable parasite, the fungus *trichophyton tonsurans*. The division of the subject into *tinea tonsurans*, *tinea sycosis*, and *tinea circinata*, is a rational one, not only on account of facility of description but also because each affection has a specific and distinctive clinical history, and requires varying modifications of treatment. The subject of this report came to my office on November 20, 1899, giving the following history :

M. L., age 18 years, mechanic; work confined to brass and copper. Residence, Rome, N.Y.

Family and personal history negative.

The trouble for which he consulted me began about ten days previous, when he noticed a small, hard, red swelling on the inner side of the right forefinger, close to the root of the nail. The smarting and pruritus were intense, and on this account he visited the family physician, who told him that his trouble was "the effects of taking cold in a bruise." Receiving no benefit after several days' treatment, he came to my office. The inflammation had then extended around the whole base of the finger nail, and caused severe suffering.

On the back of the hand two or three intensely red papules were seen. On the forearm was a larger papule, and starting from it, distributed in a semicircle, several smaller ones. It was the appearance of the latter that aroused my suspicions and led to a more careful inquiry. He then told me that his home was two or three miles from the city, and it was the custom to drive the family horse to and from work; that the horse which he had been driving had a sore on the shoulder, and he had been cleaning the sore by the use of soap. Careful examination revealed no other spots on the patient's body.

A microscopic examination of the skin-scraping with several of the fine hairs from the points of attack on the forearm was then made. *Trichophyton tonsurans* was found in the first specimen.

The following week the patient called my attention to a

"rash" on one of his legs. Examination disclosed the typical lesion of *tinea circinata*. On coming to my office a few days later, the man was accompanied by a child four years of age. He said "that he brought his brother, that he might show me a sore which had been on the little fellow's head for some time and which, of late, was getting larger."

Examining the child's head, a swelling the size of a silver dollar was found. It was markedly elevated, edges abrupt, boggy almost to fluctuation, and the surface covered with pus, through which the lusterless, broken hairs were projecting. These were very loose, pulling out with scarcely any force whatever. We had, in fact, the perfect appearance of a kerion.

Examination of these hairs under the microscope showed mycelium and spores of the infecting parasite. The question then arose, might not the infection on the young man have come from the child, as the sore appeared on his head before his attention was called to his own finger, and the sore on the horse been of some other nature? Questioning the patient gave no positive evidence, so the horse was examined and some of the hairs from the sore taken for a microscopic examination. *Trichophyton tonsurans* was found. The

family are positive the sore appeared on the horse before any of the children were attacked. Therefore I am positive the original infection came from the horse. Most authors state that the parasite may be transmitted from the lower species to the human body, but on reviewing the recent literature on the subject only one authentic case was recorded. This was reported by Wechselmann in the *Berliner klinische Wochenschrift*. He presented a case in which a child became infected with the disease from playing with a dog affected with the same disease. Both in the child's and the dog's hair mycelia of the *trichophytes* fungus were demonstrated.

A few words in regard to the diagnosis. Later in this same family occurred two other cases of the same disease, illustrating the infectiousness of the parasite. The first was in a boy 7 years of age, the second in a girl 14 years old. The father and mother were not attacked. The older children yielded more readily to treatment than the younger. The microscope was resorted to in all the cases for the purpose of a diagnosis. The history of a case in the parasitic forms of skin disease is of great help, but my opinion is, that a positive diag-

nosis cannot be made without resorting to the use of a microscope.

The first case reported, that of the older boy, illustrates the inestimable value of a microscopic examination. The manner of the attack in his case, the tinea unguinum, is considered by all authorities to be the rarest form. Without resorting to the method here suggested, it would have been absolutely impossible to have made an early diagnosis.

A NEW PHOTOGRAPHOMETER.

By JOHN MILTON GARRATT, M.D.,

of Buffalo, N. Y.

To picture a bodily deformity graphically so that the description will be of practical utility in studying the development of a given case is an art in which the

majority of the medical profession are none too proficient, and many who possess the ability are frequently so pressed for time that the description suffers in the loss of many important details which later might assist in a better understanding of the case.

Many instruments have been invented to facilitate the measurement of the degree of deformity; they are, however, more or less complicated and difficult of application, and all time-consuming. Mention may be made of the Scoliosometer of Mikulicz, the Orthopedic Goniometer, and the Beeley's Square and Plumb Line. The measurements thus obtained are usually recorded upon a diagram.

Photography has been resorted to by many and with advantage, for, if the technic has been carefully carried out, a faithful and permanent record is obtained. The objection to an ordinary photograph is the absence of definite measurements.

It is the purpose of this article to introduce a device which will make it possible to include this desirable feature—an addition which will conduce to perfect records, and with an expenditure of a minimum amount of time and energy. I have given it the name photographometer, a term which suggests its use. It consists of threads, black and white, placed equidistant so as to form perfect squares of one inch. The black thread is intended to designate feet; the white, inches. The threads are strung from hooks driven into the vertex of the angle formed by the glass-retaining projection and the inside of a solidly made picture frame. To preserve perfect squares it is of course necessary that the threads be strung all from the same side of the hooks. A frame secured, it is best to measure off the exact center on each of the four sides. Then pin in place a cloth tape measure, and from the center mark the inches with a short stroke of a pencil, the feet with a long stroke. Next the hooks are placed, then the threads strung. Coates' No. 8 in black, and No. 13 in white, will give good results. The black is placed first, beginning from the center; string this to the opposite center hook. Next form the white squares. All squares may be formed without destroying the continuity of the thread. As to the size of the frame, this will depend upon the particular purpose for which it is intended. For general use one 4 by 5 feet will meet requirements. One can be made at but little expense and requires no great amount of mechanical ingenuity. In the practical application of the device the precaution should be taken to have the frame and camera upon the same plane, otherwise the squares are likely to be distorted. It is convenient to suspend the frame by means of rods with hooked ends to a wire,—rod adjustment being allowed for by the use of thumb-screws fastened into the lateral sides of the frame. The wire must be quite taut to prevent vibration. It is of course understood that the apparatus is to be placed in a good light.

The accompanying illustration is intended to elucidate the application of the device.

Phosphorus Poisoning.—Guthrie (*New Orleans Medical and Surgical Journal*, November, 1900) reports a case of phosphorus poisoning occurring in a child 2 years of age. The child had eaten a piece of bread on which was spread a vermin exterminator, in the form of a paste composed mainly of phosphorus. The child vomited and had profuse watery stools. There was stupor, the pulse was rapid, but the rectal temperature was normal. Drugs to combat the effect of the phosphorus were given and lavage employed; but the child died the following day. Necropsy showed the heart and the cells of the liver and pancreas undergoing marked fatty degeneration. The kidneys showed the most marked pathologic changes, cloudy swelling was seen throughout the renal epithelium, in both cortex and medulla. In Bowman's capsule there was a marked separation of the 2 layers of epithelium. The parietal layer of Bowman's capsule showed a desquamation of cells forming it, the cells being degenerated and peeled up from the cavity which they lined. The shrinking of the glomerulus and increased opacity of epithelial layer of cells covering capillary tuft is characteristic of the acute desquamative nephritis of phosphorus and arsenic poisoning, and of yellow fever. Section through secreting tubules, whether in cortex or medullary portion, showed the same granular and hazy condition of all cell-substance and indistinct cell-outline. In some of the tubules the cells lining them were completely broken down and blended. The findings in the urine were such as would be expected from this condition of the kidney. [A.M.C.]

VOL. VI, No. 26

DECEMBER 29, 1900

\$3.00 PER ANNUM

The relative merits of slow sand-filtration and mechanical filtration are intelligently and dispassionately considered in a report made recently by a special committee of the Medical Society of the District of Columbia and presented to the Senate of the United States by Mr. Gallinger. The necessity for filtration on a large scale of the water of the Potomac River resides in the high death-rate from typhoid fever in the District of Columbia—namely, 221 for the year ended June 30, 1900, with an average of 199 for the preceding 10 years. It may be estimated that for every death from typhoid fever there are 10 cases of the disease, so that on a conservative basis the pecuniary loss to the community may be placed at \$1,000,000 per annum. Now, it has been shown that wherever a proper system of sand-filtration for the water-supply has been installed the mortality from typhoid fever has been reduced from 50 to 75%, while the results from mechanical filtration have not been quite so satisfactory. This is in accord with the demonstrated greater bacterial efficiency of sand-filtration. On the other hand, the water is not improved by the presence of alum, for instance, even should it be shown that this is capable of no harm. It is true that the first cost of a sand-filtration plant is the greater, but the subsequent cost of operation, renewal, etc., is the less. From the foregoing considerations the committee believes it would be an unwise experiment to resort to mechanical filtration, and it earnestly and unhesitatingly recommends the prompt installation of natural sand-filters.

Tenement-House Legislation.—A special report on housing-conditions and tenement-laws in leading American cities, based upon personal observation, investigation by correspondence, and a study of laws and ordinances, has recently been made by Mr. Lawrence Veiller, secretary to the New York Tenement-House Commission. Appended to the report is a comparative table showing the most important provisions of the different tenement-house laws in each of 27 cities, grouped together side by side. It appears that none of these large American cities, excepting New York, Boston, Cincinnati, Jersey City, and Hartford, really has a tenement-house problem, while in the great majority the tenement-house, as known in New York, does not exist, the people of restricted means living generally in small one-story or two-story houses, containing one or at most two families, while in many

cities the houses are owned by the workingmen themselves. A number of cities exhibit bad housing conditions, giving rise to what might be designated a housing problem, but this is in no sense comparable to the tenement-house problem as known in New York and Boston. The laws of Buffalo, Philadelphia, and Washington might, in many respects, well serve as models for New York, especially with regard to the provisions for light and air. The Buffalo law provides that "no court or shaft shall be less than 6 feet wide for one-story or two-story buildings, and at least 8 feet wide for three-story and four-story buildings, and 1 foot wider for each additional story above the fourth story." The law in Philadelphia provides that "no shaft or court shall be less than 8 feet wide in any part, and that any court or shaft between the wings of a tenement-house or between two tenement-houses shall not be less in width than 13 feet; and all such shafts and courts shall be open on one side from the ground to the sky."

If these provisions are contrasted with the present provisions of the New York law, which permit, instead of wide shafts, of mere slits 28 inches wide and 60 feet long, and closed in on all four sides, it will be realized that New York is in some respects far behind many smaller cities in her tenement-house laws.

A Paradise of Spinsters.—The celibate tendency of the modern woman is beginning to worry the vital statistician. The decadence of marriage is threatened, and the gradual extinction of the race. Mr. Carroll D. Wright has been investigating the subject, and finds that of 17,427 representative workingwomen, living in 22 cities, 75% of them being under 25 years of age, 15,337 were single women. These figures are simply appalling. In the good old times, it is claimed, one-half of these young women would already have been married from 3 to 5 years. The fact seems to be that there is a tendency to the postponement of marriage on the part of both sexes. In the case of women this postponement is too often fatal, and in the case of men it gets to be a bad habit. But the evil being recognized, and reduced to figures, the next natural thing to do is to seek for the causes of it.

Several theories have been advanced to account for this increasing unpopularity of marriage. The statement that young men have become more shy and embarrassed in the presence of the modern go-ahead

girl, may have some truth in it. The present tendency is undoubtedly to cultivate self-assurance and independence in young women, and to encourage them to become self-supporting. Many avenues are open to them; they can make a comfortable living and enjoy life. Many a woman, in fact, can make a better living for one than the majority of young men can make for two (with prospects of more). This situation tends to check marriage in two ways: First, it makes the women more independent of men, and therefore, in the second place, perhaps a trifle less attractive to them. Marriage is an odd affair, anyhow. It is largely a psychical business at the start, based upon a delicate emotional instinct; and all the logic and reason of a progressive age cannot alter that fact. The pushing and business-like modern woman is not conducive to it.

The competition and the stress of modern life are deterrent to matrimony. Every one can see this in his daily observation. How few men are able properly to marry before they are 35 or 40. But by this time the girl companions of their youth are almost fitted to become grandmothers. We would suggest to Mr. Wright that he should write up the statistics of bachelors—both young and old (if any of the latter can be found). In France a law has been introduced into the Senate to tax all celibates over the age of 30, and all married couples who remain childless after 5 years. We heartily approve of this plan. Let these people contribute to the support of other people's families if they persist in not having any of their own.

The Pathogenesis of Arthritis Deformans.—Dr. A. O. J. Kelly in a recent paper (*Journal American Medical Association*, December 22, 1900) discusses this subject at considerable length in the light of the latest investigations. After referring to the two chief theories of the disease (the neural and the bacterial) he expresses the opinion that arthritis deformans is an infectious trophoneurosis. Schüller first suggested the infectious nature of the disease, and demonstrated in the diseased joints a bacillus with polar staining, with cultures of which he produced in the joints of animals lesions similar to those observed in the joints of man. Other observers, notably Bannatyne, Wohlmann and Blaxall, Chauffard and Ramond, and von Dugern and Schneider, have also claimed to have found a microorganism, although these bacteria are probably not all identical. The last two observers found a small diplococcus in the gallbladder, which in cultures produced in rabbits lesions identical with those found in human subjects. The development of the chronic polyarthritis deformans is attributed by them to infection from a chronically inflamed gallbladder.

The purely nervous theory of this and allied diseases was held originally by the late Prof. J. K. Mitchell, of Philadelphia, and though in its entirety it cannot be supported in the light of modern bacteriology, it was

yet a remarkable instance of prescience in pathology. This fact, it seems to us, is abundantly shown in Kelly's paper, for although this author does not accept the theory of Mitchell, he yet points out how many of the symptoms of the disease are essentially neurotic in origin. These symptoms are especially the muscular atrophy and the irritation of the nerve-fibrils, as indicated by pain, glossy skin, and edema. Certain trophic lesions also, such as erythema, mottling of the skin, pigmentation, and scleroderma, are identical with those that are observed in peripheral nervous disorders. The spinal cord does not seem to be involved, and here is one of the points of widest divergence from Mitchell's original theory.

According to Kelly, the local habitat of the bacillus is probably in the synovial membrane, and the changes in this membrane are the immediate effects of the specific action of the bacterium. From this seat the production of toxin proceeds, and these toxins are the causes of many of the so-called secondary effects.

The Teaching of Anesthesia.—All experienced surgeons realize the great importance of a careful administration of anesthetics. And all physicians at some time during their professional careers are likely to be called upon to administer anesthetics. In spite of the need of experience and of special knowledge for the successful administration of anesthetics very little attention is paid to the subject in most of our medical schools and in hardly any, if any, is there an opportunity for gaining a practical knowledge of the subject. Even in England, where professional anesthetists are generally employed, it seems that the attention paid to the subject has not been very great in the past. In a letter to the *Lancet*, November 10, 1900, Dudley Buxton, lecturer on anesthetics in the University College Hospital, London, expresses his satisfaction that more attention is being paid to this subject in the English medical schools than formerly, and emphasizes several important points in this connection. He believes that it is absolutely necessary for students actually to give the anesthetic under supervision during their instruction and that physicians and surgeons should recognize the importance of the subject. The students should not only give the anesthetic but should examine their patient before and after its administration; they should study any noteworthy differences from the normal and be taught to make a careful choice of anesthetic.

The skilful anesthetist should have sufficient knowledge of medicine to conduct an accurate physical examination, including that of the blood and secretions. His familiarity with surgery should enable him to know what the operator requires and what will be the effect of the operator's manipulations upon the patient under anesthesia and also the requirements as to relaxation of the patient for special operations. His knowledge of anesthetics should be such that he can adapt

the anesthetic to the necessities of the patient and the requirements of the surgeon. The old days have gone by when anyone from the house-surgeon to the ward-nurse can be considered competent to administer anesthesia, while the operating surgeon "keeps his eye on the patient." The faculties of our medical schools should recognize the tremendous responsibility of the anesthetist and the fact that all graduates are likely to be called upon to use anesthetics and in most cases quite frequently. Lack of knowledge or skill may jeopardize the patient's life and frustrate the surgeon's most skilful endeavors. The facilities for teaching this subject should be increased; it should be made compulsory and the opportunity for hospital training should be given. In this way the students of the future will graduate much better equipped in a very important requisite than their predecessors have been.

The Examination of Public Water-Supplies.—It has not been long since the commonly accepted theory was that the purity of any source of public water-supply might be definitely and finally determined by means of a single chemical analysis. There are not wanting official reports in which after consideration of the probability of water pollution the subject has been set aside with reference to the report of one analysis by some prominent chemist, the results of which have been negative. It may seem a harsh judgment to express, but it is highly probable that in some instances expert chemists, being asked for the results of their examination, have simply given them, without explaining to the official bodies that said results were in no wise valuable in and of themselves, but should be considered as but one link, and an unimportant one at that, in a long chain of necessary evidence.

Gross pollution of a certain sort is certainly discoverable by means of chemical examinations. The chemical examination is a process which should never be omitted in any investigation of a water-supply. It is, however, of much less import than continuous daily examinations of the water by modern bacteriologic methods, and both chemical and bacteriologic methods are of much less value than the naked-eye examination of the original sources of supply and the methods of conduction and distribution.

The reason for the comparative values of these methods is to be found in the fact that the condition of the water-supply on any one day is no index of what it may be upon subsequent days. The daily variation is influenced by conditions existent upon the water-shed, at or adjoining the sources of supply and near or surrounding the system of conduction and distribution. All of these conditions are rarely operative at one time or in any regular sequence. Only the intelligent inspection of the actually existing conditions can give even an approximate idea of when or how these conditions may come into play and so influence the sup-

ply. The bacteriologic daily examination may often succeed in detecting the changes in the purity of the water after the causes have become operative. In this manner this examination may give the clue which will lead to remedial measures after the damage has been done. But perfect knowledge gained by the naked-eye inspection might have prevented the actual occurrence of the pollution.

It seems but a small requirement to put upon those responsible for municipal or private control of water-supplies that the water-sheds should be effectually and continuously policed to prevent gross contamination by drainage, sewage, or by refuse thrown directly into water courses; to add to this the daily bacteriologic examination of the waters as distributed to the general public and the establishment of certain standards above which contamination may not rise without causing public notice and warning to boil the water before it is used. The latter possibility will be practically eliminated in cities that provide efficient filtration through sand filter beds, although these need careful scientific supervision in order that the best results may be obtained.

Mental Sanitation.—Smith (*The Canadian Journal of Medicine and Surgery*, December, 1900) calls attention to the marked influence which heredity has in producing insanity, and charges that much of the so-called literature of the present day conduces to an unsettled mental state. He concludes as follows: 1. The public should be enlightened with regard to the nature of insanity in order that they may properly estimate the influence of heredity as the most potent factor in the causation of disease. 2. As a preventive measure the public should be taught that as the development of the morbid disposition is most insidious and is seldom recognized until late, the consideration of the family and personal history of the individual should demand and receive early and careful attention. 3. There must be full recognition of the invariability of individuals for bearing burdens and enduring strains. 4. Many cases of insanity are justly chargeable to the imposition of burdens beyond the capability of the individual. 5. The prevention of insanity is not promoted by merely studying the phenomena of the disease. 6. Public sentiment must be enlightened before any restrictive measures can be beneficially enforced. 7. If the conditions under which many cases of insanity originate were properly understood, many attacks of the disease might be avoided. 8. The study of child character and the careful consideration of the variability in the development of mental phenomena during the period of growth in the child are all important. 9. The steps necessary to secure the adoption of these and all other precautionary measures must first be taken by the family physician, who in the future must be prepared to advise, caution and restrain in exercising his influence in the prevention of mental diseases. 10. The burden must be adjusted to the capacity of the individual in order that it can always be carried with safety when this is possible; and when it is not possible that the line of descent of every such defection shall terminate with the individual himself. [A B C.]

Reviews.

Facts, Fads and Fancies About the Teeth. Compiled and edited by HENRY LOVEJOY AMBLER, M.S., D.D.S., M.D., Dean of Dental Department and Professor of Operative Dentistry and Dental Hygiene, Western Reserve University, etc. Pp. 310. Cleveland, Ohio: The Helman-Taylor Co., 1900.

This publication can be said to be at least unique. It is described as "a repository of information and amusement, as it contains many facts, queer and otherwise, concerning the teeth of human beings; also a collection of witty and humorous sayings gathered from all sources, while at home and abroad, during many years of professional life." It should fulfil its purpose of entertaining "some weary brother during a leisure moment."

A Manual of Diseases of the Eye. By CHARLES H. MAY, M.D., of New York. William Wood & Co., Publishers, New York. 1900.

In this manual of 406 16mo pages, the author has endeavored to set forth the fundamental facts of ophthalmology, and to cover all that is essential to the student and general practitioner, for whom the book is primarily intended. A close inspection of the contents has failed to reveal the omissions of any important facts, and in some sections, as, for instance, those upon the examination of the eye, ametropia, ocular therapeutics, and general rules for operations upon the eyes, there is much practical information not always found so clearly stated in more pretentious works. There are 213 original illustrations, including 12 colored plates, a full table of contents, and an excellent index.

Laboratory Directions for Beginners in Bacteriology. By VERANUS A. MOORE, B.S., M.D., Professor of Comparative Pathology and Bacteriology, New York State Veterinary College, and of Bacteriology, Cornell University Medical College, Ithaca, N. Y.

This little volume, which is recommended for beginners in bacteriology, should certainly fill very creditably a need of the teacher and learner. It is an admirable volume not only as the name indicates for beginners, but advanced students in the science will also find it of value for reference upon certain points. It is practically up-to-date as to the technic advised. The minutest details are set forth, even to the wiping clean of tubes after sterilizing, and, as details constitute the science of bacteriology, the book should be of great help to many students and those who have been graduated a few years and come back to take up the study.

A Pocket Textbook of Diseases of the Eye, Ear, Nose and Throat, for Students and Practitioners. By WILLIAM L. BALLINGER, M.D., Assistant Professor of Otology, Rhinology and Laryngology in the College of Physicians and Surgeons, Chicago, etc., and A. G. WINTER, M.D., Professor of Ophthalmology and Otology in the Chicago Eye, Ear, Nose and Throat College. Philadelphia and New York: Lea Brothers & Co., Publishers. Cloth, \$2.00, net; flexible red leather, \$2.50, net.

This is a compendious, practical manual of 525 small octavo pages with 150 illustrations and 6 full-page colored plates. The section on the Eye is the work of Dr. A. G. Winter, while for the text relative to the ear, nose and throat, Dr. W. L. Ballinger is responsible. An enormous amount of sound, practical, elementary information relative to these subjects has been put in a small space. Long discourses on descriptive anatomy have been wisely omitted, and in their place have been substituted numerous diagrams and anatomic figures from Testut, Merkel, Zuckerkandl, Politzer, Gray, and other well-known authors, with appro-

priate explanatory legends on the plates. In their endeavor to be concise the authors have dwelt too briefly upon several subjects of prime importance to the general practitioner, notably refractive errors, the use of cycloplegics, and the consequences of continued eye-strain. A notice of this book is not complete without mention of the beautiful typography, ideal as to size, of type, black letters, spacing, leading, ink, and printing, and the excellence of the paper and binding.

Öffentliche Massnahmen gegen ansteckende Krankheiten, mit besonderer Rücksicht auf Disinfection. Bearbeitet von Dr. TH. WEYL, Privatdozent der Hygiene a. d. kgl. techn. Hochschule, Berlin-Charlottenburg. Mit Beiträgen von Hafenarzt Dr. Nocht, Hamburg, und Direktor Dr. Schwarz, Stolp i. P. Mit 57 Abbildungen im Text.

Public Measures of Protection Against Contagious Diseases, with Especial Reference to Disinfection. Compiled by Dr. TH. WEYL. With Contributions by Post-physician, Dr. Nocht, and Director Dr. Schwarz. 8vo, pp. viii, 216, 16. Jena: Gustav Fischer, 1900. Price, 6 marks (\$1.50).

A book of this sort is especially to be welcomed at the present time, when such strenuous efforts are being made everywhere for the repression of disease in all its forms. The promise of success in this direction is naturally greater with reference to those disorders whose exciting agents are known or suspected to consist in minute forms of life which can be destroyed outside the human body or whose access thereto can in one way or another be prevented. Herein reside the essential principles of prophylaxis, namely, isolation and disinfection. Preventive medicine has always been practised in some form, but the end of the nineteenth century marks an era in this department of activity that bids fair to lead in the progress of time to results of immeasurable importance and value.

The volume before us is the thirty-ninth instalment of a *Handbook of Hygiene* by Dr. Weyl. The subject matter is considered under two headings: Measures for the Prevention of Epidemics and Disinfection. Under the first are discussed (a) general measures, (b) special measures directed against individual diseases; and under the second (1) general considerations, (2) disinfectants, (3) application of disinfectants. The publication is one that should appeal especially to hygienists and to all those interested in the practical prevention of disease.

Uric Acid as a Factor in the Causation of Disease.

A Contribution to the Pathology of High Blood Pressure, Headache, Epilepsy, Mental Diseases, Paroxysmal Hemoglobinuria and Anemia, Bright's Disease, Diabetes, Gout, Rheumatism, and other Disorders. By ALEXANDER HAIG, M.A., M.D., (Oxon.), F.R.C.P., Physician to the Metropolitan Hospital, and the Royal Hospital for Children and Women, etc. Fifth edition. With 75 illustrations. Pp. xvi, 846. Philadelphia: P. Blakiston's Son and Co., 1900. Price, \$3.

Whatever one may think of Dr. Haig's views he cannot but admire the industry with which he has pursued his inquiries and the persistence with which he has maintained his opinions; and while it is not always easy to follow his argument or to accept his deductions, it must be admitted that he has given a strong impetus and has contributed a general share to the study of metabolic disturbances. Haig was himself for many years a sufferer from migraine, the attacks of which, after trials of many variations in diet, he succeeded in diminishing in both frequency and severity by the avoidance of butcher's meat. As a result of this experience he was at first inclined to attribute the disorder to the generation of some poison, perhaps a ptomain, in the intestines in the process of digestion of butcher's meat, but further study suggested a relationship with gout and then the possibility of uric acid as the noxious material suggested itself. Finally, careful examination of the urine disclosed a

distinct connection between the headache and the excretion of uric acid. It was found further that with the headache there are associated also a slow pulse of high tension, coldness of the surface and extremities, mental depression, and disinclination to activity, mental or bodily, while the urine is scanty and of high color and specific gravity. It is not believed that the uric acid is generated in the body in excess, but that it is derived from the food, while the morbid manifestations due to its retention and use are to be prevented by the avoidance of food containing uric acid in large amount and relieved by favoring elimination. The 18 chapters in which the volume is divided deal successively with the following subjects: I. History. II, III. Formation and Excretion of Uric Acid. IV. Uric Acid and Metabolism. V. Uric Acid and the Circulation. VI. Headache. VII. Epilepsy, Convulsions, and Hysteria. VIII. Mental Disease, Fatigue, and Syncope. IX. Asthma and Bronchitis. X. Dyspepsia and Gout of the Intestines. XI. Raynaud's Disease. XII. Paroxysmal Hemoglobinuria and Anemia. XIII. Albuminuria and Bright's Disease. XIV. Glycosuria and Diabetes Mellitus. XV. Gout. XVI. Rheumatism and Morbus Cordis. XVII. Treatment. XVIII. Instruments and Methods. It need hardly be added that no clinician should be unfamiliar with the work of Haig.

Hand Atlas of Human Anatomy. By WERNER SPALTEHOLTZ, Extraordinary Professor of Anatomy in the University and Custodian of the Anatomical Museum at Leipzig; with the Advice of Wilhelm His, Professor of Anatomy in the University at Leipzig. Translated from the third German edition by Lewellys F. Barker, Professor of Anatomy in the University of Chicago; with a Preface by Franklin P. Mall, Professor of Anatomy in the Johns Hopkins University at Baltimore. Volume I: Bones, Joints, Ligaments. Pp. 235, with 280 illustrations, many of them full page and colored. Leipzig: S. Hirzel; New York: G. E. Stechert, 1900. Price, \$3.50.

An English edition of this splendid atlas which has for the past five years been well known to students of anatomy who are readers of German will be welcomed by students and professors of anatomy and all interested in this important branch. Good atlases of human anatomy published with English descriptive text have been singularly lacking when we consider the large number of such books which are in use by continental students of medicine. Dr. Mall rightly calls attention in his preface to the importance of a mental image of the human body rather than an effort on the part of the student to memorize numerous terms as is too often the case in American medical schools. The importance of this can hardly be overestimated. Of course a complete mental image comes only after numerous careful dissections, but illustrations of the proper character are of the greatest aid. This series of hand atlases is to be published in four volumes and it embraces the entire descriptive anatomy with the exception of histology. The number of drawings for the entire series is roughly estimated at about 800, but judging from the number in this volume (280) it seems likely that this estimate will be considerably exceeded. All the illustrations with few unimportant exceptions are from new original drawings. The text is descriptive of the drawings and occupies about the same amount of space. The new nomenclature which was adopted at the ninth meeting of the German Anatomical Association in Basel, April 19, 1895, is adopted, but in the translation where the terms used are very different from the old nomenclature the latter are inserted in brackets. We believe that the adoption of the new nomenclature is a matter of great importance. There has been considerable confusion of anatomical terms in English texts and many improper and unnecessarily complicated terms are now in use. The fact that it has been adopted by the Germans, who are the most progressive anatomists of the present time, makes it probable that it will soon be generally adopted by all scientific anatomists. For beauty, clearness, and accuracy of illustration we know of nothing which has appeared in so compact a form which in any way compares with this hand atlas. The profusion of illustrations may be shown by referring to the description

of the lower jaw, which is depicted by a full-page cut showing the appearance from below and large cuts showing the outer surface and inner surface, outline cuts with the muscular attachments depicted on the inside and outside of the bone, and four cuts showing the appearance of the bone in the newborn child, the child at seven, the adult, and in old age. The hipjoint is depicted in five cuts nearly life size, from in front with the capsule complete, from behind with the capsule complete, from behind with the superficial layer of the capsule removed, from the medial side with the bottom of the acetabulum chiselled away sufficiently to make the head of the femur visible and in frontal section. The descriptive text will be sufficient to the needs of most students of anatomy and possesses the most important essential, accuracy, although in some cases it lacks somewhat in fulness. The work of translation has been admirably done, and as the cuts are printed in Germany in the same manner as the original, they do not suffer from appearance in the English edition. In making this atlas accessible to English-speaking students who do not read German, Dr. Barker has rendered a valuable service. We feel sure that the atlas will have a large sale, although the expense connected with the preparation of fine cuts and a tariff which discriminates against scholarship and education make the price somewhat high.

A Manual of Otology. By GORHAM BACON, A.B., M.D., Professor of Otology in Cornell University Medical College, New York, etc., with an introductory chapter by CLARENCE JOHN BLAKE, M.D., Professor of Otology in Harvard University. Second edition, revised and enlarged, with 114 illustrations and 3 plates. New York and Philadelphia: Lea Brothers & Co., 1900.

The philosophic as well as very practical introductory chapter by Professor Blake, of the Harvard Medical School, should be carefully read by every general practitioner as well as every aurist in the land. It is here shown that otology like microscopy cannot be taught by lectures, but must be learned by long and patient clinical study of abundant material, and as it were at the elbow of the teacher.

Dr. Bacon has done his part admirably also. He shows the general practitioner and the student of medicine, what ought to be done and how to do it. It is important that the general practitioner should know what ought to be done for ear disease even if he cannot carry out the treatment, and he should remember that he sees cases very often in which hearing and life itself are dependent upon a prompt recognition and treatment of an otitis and its sequels. If he cannot fulfil these demands, he must bear in mind that there are those in every large community who can. The author devotes considerable attention to disease of the nares and nasopharynx in their relation to aural disease. We would be glad to see more stress laid on pneumomassage of the membrana tympani, and less on inflation of the tympana in the treatment of chronic aural catarrh. The latter operation is always in our opinion too much of a shock to the middle, as well as the internal ear, to be of any value. It is always a procedure disagreeable to the patient and may convey septic matter from the nasopharynx to the middle ear. Pneumomassage of the external auditory canal is never disagreeable nor septic, and always gives more or less relief to the ear at once, and finally brings about permanent relief when inflation fails entirely.

Chronic purulent otitis media and its grave intracranial sequelae are given a careful consideration, and the methods for carrying out their rational treatment are set forth in a masterful style. We know of no manual of otology, of equal size and volume, within such easy reach of the practitioner and student of medicine. The publishers have done their part of the work in their usual beautiful and substantial manner.

Influenza in Russia.—The influenza epidemic is reported to be very severe in St. Petersburg, and the changeable weather, snow and slush alternating, conducive to its spread. A meeting of physicians was summoned to discuss remedies, but very few responded to the call, some being overworked and others victims of the malady.

Correspondence.

THE EDUCATED SUICIDE'S BRAIN.

By B. G. WILDER, M.D.,
of Ithaca, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:

THE very appreciative Editorial Comment, "The Educated Suicide's Brain," in your issue for November 17, contains two misapprehensions which I will try to correct.

First, the error (as I now regard it) in the original interpretation was due mainly to the unusual length of a fissure resulting from the junction of the postcentral with the subcentral.

Secondly, I avoided committing myself to an acceptance of the two other reported instances of central reduplication. Calori's is known to me only through Giacomini, and the latter's figures are unsatisfactory, especially in that they do not exhibit the topographic relation of the paracentral fissures to the alleged second central.

Upon the whole, with all deference to the anatomists just named, I now think that a genuine case of reduplication of the central fissure is yet to be observed.

NOTE.—After the above was sent the kindness of Dr. D. S. Lamb enabled me to consult the "Nota preventiva" of Leggiardi—Laura, "Duplicità della scissura di Rolando nei criminali," *Arch. Psich. Sc. penali ed Antropol. crimin.*, Torino, xx, 421. Six cases are claimed, but in the absence of figures and detailed descriptions I must refer them to the same category as my own.

DRAINAGE IN APPENDICECTOMY.

By G. S. BROWN, M.D.,
of Birmingham, Ala.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

AS AN excuse for touching upon this apparently threadbare theme, I have to suggest at least one exception to the very good rule of discarding drainage after appendicectomies. To close such a wound without drainage and have the patient out in two weeks with no danger of a hernia or fistula is very satisfactory, but it does not warrant eminent surgical teachers making use of such expressions as, "throw away your gauze drains," and "never use drains after appendicectomies." Such expressions from such sources are capable of, and undoubtedly have, already wrought disaster in more than one instance. Such expressions, like most of the old saws and proverbs, need qualifying; because, as they are often merely products of the phrase-making habit, they may, if not properly qualified, be followed by loss of human life. The following case illustrates how *sometimes*, "the more haste the less speed" may apply in this matter of drainage, and it also represents my nearest approach to a grave disaster, attributable to dispensing with drainage:

Mrs. C., who gave a history of two mild attacks of appendicitis and one severe one during the preceding year, was taken sick at 6 P.M., April 26, with severe colicky pains which lasted all night. A physician was called in at 6 A.M., April 27, and gave her morphia. The symptoms were all much better all day except that she had a little fever and a suspiciously rapid pulse. At 6 A.M. of the second day she had a chill, followed by marked collapse and cyanosis, but from which she quickly rallied. At 3 P.M. she had another similar attack during which her pulse was 160 and temper-

ature 103.5°. She again quickly rallied from the collapse and at 7.30 P.M., when I was called in consultation, the pulse was 120 and temperature 103°. It was thought she had a gangrenous appendix and removal to hospital and operation was at once advised.

This was done at midnight. A somewhat enlarged but nonadherent appendix was removed; there was no localized peritonitis, not even of the serosa of the appendix itself, and although the mucous membrane of the appendix was gangrenous, there seemed no infection on the outside at all, and it was thought safe to close the wound without drainage. After the operation the temperature and pulse remained nearly at the normal point for 5 days. On the sixth day the temperature was 100°, and pulse 100. The seventh day, in the evening, the temperature was 102°, pulse 110, and a stitch-abscess containing foul pus was found at the upper angle of the wound. (Owing to the patient being very fat this was the pendant end of the wound.) A few of the stitches were cut and the next morning the temperature was down, but the evening temperature of the eighth day was 102°; the wound was opened in its upper half, but it did not have any apparent communication with the abdominal cavity. At this time the woman began to complain of a pain under the right costal cartilages, and on the ninth day she had a marked and most alarming collapse, and that evening at 9, with her temperature 104° and pulse near 200, she was put on the table, and while salt-solution was being given under each breast, the original incision was prolonged down through the lumbar muscle until the right kidney was exposed. The peritoneum behind the colon was exposed and opened and several ounces of serum let out; adhesions of greenish lymph were broken up and the track followed up under the liver to the region of the bile-ducts and there a small quantity of foul greenish pus was found, traceable all the way from the iliac fossa.

All the infected region was packed with gauze and the wound dressed, but as the patient was pulseless at the wrist, and the heart beating about 200, she was kept on the table about 2 hours longer while stimulants were administered.

The patient rallied in a few hours and then rapidly convalesced, but it was 2 weeks before the gauze came away. The gauze left a fistula which discharged bile for 3 weeks and then persisted as a mucous fistula for 2 months longer. This infection came, most probably, by the stitch abscess, although it might have been caused by the gravitating of the postoperative fluids along the iliac fossa and a slow growth of the germs. In either case a drain of the smallest size, covered with rubber tissue and reaching down to the iliac fossa, would have carried off the postoperative fluids both of the iliac fossa and of the abdominal wound, and would have prevented all secondary infection.

It would certainly seem rational to leave in such a small drain (removable at the end of 24 hours if deemed advisable) in all cases where either the symptoms or the local signs would indicate any danger of infection; certainly such drainage can only delay convalescence a few days and may, in a few cases, save life.

In the case reported the patient was watched very closely on account of the violence of the early symptoms and the fact that the inside of the appendix was gangrenous. Drainage had been dispensed with because the serosa did not seem to be infected at any point. The infection was probably caused by contamination of the abdominal wound in cutting off the appendix, the formation of a stitch-abscess, and secondary infection of the abdominal cavity by means of the through-and-through stitches used.

Both the early and late symptoms suggested strongly that the streptococcus was the infecting agent, though unfortunately no culture was taken, and it was only by prompt and radical action, justified by our strong conviction as to the nature and seat of the trouble, that the case terminated so fortunately.

However few cases of this kind there may be, they prove exceptions to the rule, viz., "that it is best, as a rule, to dis-

pense with drainage after appendicectomies." It also suggests that this *rendering* of the rule, while less dramatic perhaps, is also less dangerous, than "throw away your gauze drains" and "never use drains after appendicectomies."

GILLIAM'S ROUND LIGAMENT SUSPENSION OF THE UTERUS AS A DISTINCTIVE OPERATION.

BY D. TOD GILLIAM, M.D.,
of Columbus, Ohio.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN his last communication (November 24, 1900) relative to the question at issue between us, Dr. Carl Beck says: "If he (Dr. Gilliam) intends to convey that this last modification of mine differs from the one which he describes as his own, he is perfectly right, because what he published was not my modification, but my original operation." What Dr. Beck's original operation was, I have no means of knowing, as I have never seen a description of it, and if, as claimed by him in his first communication, my operation tallies with his in every detail of the steps of the operation I will at once renounce all claim to originality so far as this operation is concerned. The only way to determine the matter will be for Dr. Beck to furnish a description of his original operation and place it alongside that of mine and compare them. Dr. Beck may be, and for aught I know is, entitled to priority in the matter of fixation of the round ligament in the anterior abdominal wall, but that does not confer upon him a quit claim for all the variations or improvements that may be evolved thereafter, much less does it justify him in such sweeping assertions as he has made with reference to my operation.

Evidently Dr. Beck read my paper in a mood of mental abstraction, else he could not have made an assertion so palpably incorrect. The dissimilarity of the two operations is clearly manifested in the appended comparison of the successive steps in each:

Beck draws the uterus out of the abdominal cavity.

Gilliam operates with the uterus *in situ*.

Beck dissects the round ligament from its broad-ligament attachment for a distance of 3 inches on either side.

Gilliam makes no dissection whatever, but merely places a thread under the round ligament, $1\frac{1}{2}$ inches from the uterus, by which it is to be drawn up through a puncture wound into the abdominal wall.

Beck folds the round ligaments over the fundus uteri and lays them side by side in the median incision and stitches the peritoneum under them. (Incidentally this leaves 3 little chinks for nosing intestines to hang themselves in, 1 between the folded ligaments and the fundus and 1 on either side between the round and broad ligaments.)

Gilliam makes a little puncture through the muscle and peritoneum at either side of, and an inch from the margin of the median incision and draws the ligament into it by means of the thread spoken of above. This leaves an opening 6 or 7 inches in circumference which is too large for strangulation, and the laxity of the attachment allows the uterus to rest on the bladder in easy repose.

Beck dissects a strip from the rectus muscle on either side, cuts it loose at one end, runs it through the loop of the ligament and unites the muscle again by suture.

Gilliam cuts no muscle, but simply fixes the ligament in the perforated wound by a single catgut suture.

If Dr. Beck can see a parity in "the details of every step" of the two operations, he is endowed with a keener perception than I can lay claim to. Perhaps Dr. Beck lays claim to my operation on the score of priority in anchoring the round ligament in the anterior abdominal wall. This is very different, but if he had made this claim I still should have contested his right to appropriate to himself all the variations and improvements in technic that might be evolved by his successors. On the same basis he would lay claim to the technic of Ferguson of Chicago, Noble of Atlanta, and perhaps others to come. Following this claim to its legitimate conclusion, the surgeon who first made an abdominal section would be sole claimant to the whole realm of abdominal surgery. There would be no Baer, Goffe, or Kelly in hysterectomy; no Wylie, Mann, or Dudley in internal, nor Edebohls, Kellogg, or Goldspohn, in external shortening of the round ligaments. There would be no way of designating the variations in technic in any operation, except by full description of the same. If a surgeon were to do the Beck operation and claim to have done the Ferguson operation, because the Ferguson operation was the Beck operation, I am sure that Ferguson would repudiate it. The truth is, the operations are distinctive, and no man has the right to claim the product of another's hand or brain because he happened to be first on the ground.

If Dr. Beck can establish priority in the matter of fixing the round ligament in the anterior abdominal wall, it would not be amiss to designate such cases in general as the Beck operation, or to use hyphenated names to designate the modifications of the same, such as the Ferguson-Beck, Gilliam-Beck, but in the absence of positive evidence that Beck was the originator of this basic feature of the operation, no such concession could be expected. In conclusion I will say that the designation: "Round ligament ventrosuspension of the uterus" was of my own coinage, and this is the name by which the operation is generally known in this country.

FOUR CASES OF DEGENERATIVE TISSUE CHANGES FOLLOWING EXPOSURE TO HIGH TENSION ELECTRICAL CURRENTS.

BY ARTHUR CONKLIN BRUSH, M.D.,
of Brooklyn, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE action of the ordinary low tension electrical currents, such as are employed in medicine, has been known for many years and their power to cause profound tissue changes if long continued either by altering the circulation or causing electrolysis is well established; but the employment of strong high tension currents for various purposes is of such recent date, that our knowledge of even their immediate effect on the tissues of the body is very meagre; and as to their ultimate effects practically none. From a study of a number of cases and of the literature of this subject it would appear that the most frequent result from such exposure is some form of hysteria due to the fright which the mysterious nature and the knowledge of the occasional fatal action of the current engenders. Beyond this result our knowledge of the immediate results may be summed up as follows: that high power currents may produce death, no results, burns, shock, and a variety of functional disturbances of the nervous system; that slight shocks may produce local pain, numbness and paresis of an extremity with headache, ver-

tigo and disturbances of vision; that after slight shocks recovery usually occurs, but deep-seated emotional disturbances of the nervous system may persist; that severe shocks produce coma with dilated irresponsive pupils, stertorous breathing and pallor, followed by tonic and clonic convulsions, fever, and a high tension pulse; that in fatal cases there is found congestion of all the internal organs, echymoses in the skin, a fluid condition of the blood, and echymoses in the floor of the fourth ventricle; that the current kills either by direct action on the tissues or by reflex action on the nerve centers producing cardiac and respiratory arrest, cerebral anemia, and vasomotor paralysis, and that currents of high power cause direct coagulation of the cell constituents of the body. As to the ultimate results of exposure to such currents which do not kill I have been unable to find any literature, but it has been my good fortune to observe the results in four patients who had been so exposed, and in whom the condition followed directly after the exposure, and in whom there was no other discoverable cause.

CASE 1.—Female, aged 20, was admitted to my service in the Kings County Hospital in September, 1898. Three years before admittance she stepped on a car-rail which had become charged from a fallen trolley wire. Previous to that time she had been in very good health. She fell to the ground and was unable to move from the rail. When picked up after several minutes she was found to be much excited, and the next day to have lost the power of motion and sensation in the lower extremities. Six days after the accident the limbs became swollen and edematous, there was complete paralysis below the knees, but there was some power in the quadriceps extensors, and all electric reactions were lost. Both superficial and deep reflexes were absent, and there was complete loss of all forms of sensation even to the faradic brush, in the feet and legs with partial loss of tactile sensation and increased sensitiveness to pain in the thighs. On admission there was found to be marked atrophy of the lower extremities, most marked on the right side, associated with marked loss of power and complete paralysis of the extensors of the feet causing double foot drop. There were no faradic reactions and only slight ones of degeneration to galvanism except in the anterior tibials where it was absent. The deep reflexes were absent. There was decided loss of all forms of sensation in the feet and legs with pain on pressure over the nerve-trunks. Since that time there has been no change in the patient's condition.

CASE 2.—Female, aged 40. She is known to have done hard work until March 17, 1897, when upon that date, it being a rainy day, she attempted to enter a trolley car and upon taking hold of a brass rail she experienced a shock, was unable to unclasp her hand and remembers nothing more until she found herself in a waiting room, the fact being that it was found impossible to release her until the pole was removed from the wire. Since that time she has suffered from screaming attacks at night, dyspnea during the day, headache, vertigo, loss of power, and pain in the right arm and leg, with poor circulation and ulceration on the right ankle. On November 22, 1899, she showed decided loss of power in the right upper extremity and to a less extent in the right lower. The arm was in the condition of flaccid atrophy with flexor contracture. There was absence of reaction to faradism in the arm, and the galvanic current after a few seconds gave rise to a tonic and painful spasm. There was diminished tactile sensibility with increased sensitiveness to pain in the right hand and lower part of the forearm. The skin of the right arm and leg was colder than the left, small punctures bled freely, and there was a small ulcer just above the internal malleolus.

CASE 3.—Male, aged 50. Previous to February 15, 1899, he is said to have been in good health and did heavy work. On that date, it being a wet day, just as he stepped on the iron doorsill of a trolley car and at the same time having hold of the brass side rail, he received a severe shock and was unable to relax his grasp until the current was turned off at the overhead switch. He was then found to be paraplegic and anesthetic, but at the end of 10 days he was able to move

his toes, at the end of the month to walk with a cane, and since that time he has suffered from loss of power and sensation in the lower limbs. Examination on December 6, 1899, showed that he walked with a marked foot-drop, that the muscles of the lower limbs were in a condition of flaccid atrophy, that the faradic reaction was absent and the galvanic that of degeneration, that the kneejerks were diminished and the plantar reflexes absent, and that there was loss of all forms of sensation below the knees.

CASE 4.—Female, aged 28. She was in good health until February, 1899, when she was seated in a trolley car. It was a rainy day, she had no rubbers, and her feet were wet. Suddenly flames came through the floor and she received, in escaping, several shocks, one of which caused her to fall. She was removed in a very excited condition and complained of pain in the lower limbs, and in a few hours she became paraplegic and anesthetic. Since that time she gradually passed into her present condition. In walking there is a marked right foot drop; the right leg is swollen, its muscles do not react to faradism and show the galvanic reactions of degeneration, the right patellar and plantar reflexes are absent, and the left kneejerk diminished. In Cases 2 and 3 muscular fibers were removed by the harpoon from the right biceps in the second and from the right calf in the third. Both specimens show the same conditions. The muscular fibers are much swollen, their striations are indistinct, and they contain fat and pigment granules.

That these cases are not simply marked hysteria, but that the patients also did suffer from organic changes in their muscles and peripheral portions of their spinal neurons is shown first by the pathologic findings and second from the character of their symptoms. This is shown by the fact that in hysteria the deep reflexes are increased and that when they are absent it is due to involuntary contraction of the opposing muscles; that in hysteria the paralysis is due to involuntary contraction of the opposing muscles; that in hysteria there is no muscular atrophy; that in hysteria the electrical reactions are normal; that in hysteric anesthesia all or one or more forms of sensation are diminished; that in hysteric anesthesia small punctures do not bleed; that in hysteric hemiplegia the leg is more paralyzed than the arm and the leg is dragged; and that trophic cutaneous changes do not occur.

Having established the fact that we are dealing with an organic lesion and not simply with a functional one, it remains to establish its nature and mode of production. If one were to see these cases without knowledge of their etiology, one would be justified in considering them as simply cases of disease of the peripheral portions of the spinal neurons or multiple neuritis, so perfectly do they present the conditions found in that disease, and as this condition is one which is due to degenerative changes in the neuron from the actions of various poisons, it is reasonable to assume that an agent which has been shown to have the power to cause coagulation of the animal cell when of very high tension might, when in less power but continued for several minutes, cause less marked immediate changes but still of sufficient gravity to be followed by secondary degenerative changes.

Another question which arises is, were the muscular changes secondary or were they also directly due to the same cause? From the unusual rapidity with which the paralysis developed it seems rational to conclude that they were directly due to and produced in the same manner as the neurotic ones.

School Hygiene.—The district government of Cologne suggests that the country school boards shall provide an appropriate number of felt and wooden shoes to be placed at the disposal of the children. By this system those who come from a distance with wet footgear will have an opportunity to exchange it for dry shoes.

Special Article.

A SUITABLE DRESS FOR DEFENCE AGAINST INFECTIOUS DISEASE.

By JOHN S. FULTON, M.D.,

of Baltimore.

THE requisites for a defensive dress are, in the order of their importance: (1) That it shall leave exposed only so much of the body as is necessary to the free use of the senses; (2) that it shall not encumber the movements; (3) that it shall be of sterilizable material, and cheap; and (4) that it shall do no needless violence to propriety. So far as I have seen them exemplified, the efforts to meet these requirements have succeeded best as to covering the body, indifferently as to freedom of motion and use of the senses, and poorly or not at all as to conventional ideas of propriety. I have been conducted about one of the best hospitals for infectious disease in this country with no protective clothing whatever, and I have shambled about another enveloped from crown to heel in clothing that would insure speedy death if it were worn upon the street. Between these extremes I have seen, and carried about, and worn, a great variety of costumes intended, if not adapted, to protect against infection. Only occasionally, when I have been called to see cases of smallpox, have I found either local officer or private practitioner provided with any sort of defensive dress.

I have at length hit upon a dress which suits me at least better than any of its predecessors. I have worn this costume, excepting the hat, on the streets of a city, from house to house, without exciting any comment, and in the house, I have been more comfortable and have given less discomfort than I did in any of my previous disguises.

The suit consists of a suit of white pajamas, a baker's hat, a pair of tennis shoes, and four rubber bands.

The pajamas come in four sizes, A, B, C, and D, cost \$1.50 a suit, and will stand considerable wear. The baker's hat costs 15 cents, and the shoes from 50 cents to \$1.50. The rubber shoes will not stand any form of sterilization by heat. For wear in a hospital or in a house, I should suggest felt slippers, made of a single piece of thick felt; they are warm and comfortable, and can be boiled, or autoclaved without injury. A suit with these slippers can be carried in a very small box. The felt slippers cost from 50 cents to a \$1.00.

It matters much how these clothes are put on and taken off. First one removes collar and cuffs, and rolls the shirt sleeves up above the elbows. This is done in preparation for washing hands and face after the visit. The trousers must be turned up five or six inches, and then the shoes are changed. Then the pajamas are put on, trousers first, and blouse outside. The rubber bands are next put on, to confine the sleeves at the wrist and the pants over the shoe tops. The hat is pulled down to the neck behind, and nearly to the eyebrows in front. The ears are half covered. The loose crown of the hat should be so disposed as to give fair warning if the head is about to make a dangerous contact. This is an important point. In examining smallpox cases I have often found that the patient's interest in his eruption has been as great as my own, and when the chest is scrutinized two heads are apt to come into contact.

When removing the clothing, be sure not to begin with the rubber bands. The hat naturally comes off first, and is turned inside out. Then remove the jacket, which if the bands remain at the wrists, will come off inverted, that is with the infected side in, as is right. The drawers also will be inverted by the bands at the ankle. When these garments are nearly off, it is necessary to grasp the ends of the legs and of the sleeves, to make sure that the rubber bands come off with the clothes. The shoes are taken off without touching the socks.

Each garment as removed is folded lengthwise and laid upon the fiber-board which is intended to make a tight round package, of a size to slip easily into the metal box. About 2 ounces of formalin may be poured upon the clothing at each end, just before it is slipped into the case. The box being

closed, a strip of adhesive plaster is applied to each joint, making the package air-tight. Then one is ready to bathe and reclothe. This package may be quite safely carried in contact with other clothing, though it cannot be worn again without a long airing. Even if the package should remain closed for a year the odor of the formalin will prove overpowering.

This is not an elaborate technic, and by no means so exact as will one day be required of us. In private houses it might be difficult to make a complete toilet. Whenever there is a bathroom the full toilet, which I have described, can be made, the coat, collars, and cuffs being left down stairs. Where there is no bathroom, one may prefer not to change shoes. If visits are to be repeated at short intervals, it may be permissible to leave a suit at the house, provided always it is kept in the safest convenient place, and in its case. The clothing suggested here is cheap enough to warrant the possession of two suits for each infected house, and a fresh suit per day per house.

When we consider the various infections against which special clothing should afford some defence, considerable dif-

ference of opinion will arise. All are doubtless agreed that in visiting cases of the less common infections, as smallpox, the ordinary clothing should be protected. If the golden rule were applied to the inquiry concerning the commoner infections, it would be agreed that the ordinary clothing should not be exposed to those infections which are thrown off by the skin and easily carried in the air, *e. g.*, scarlet fever and measles.

Of those diseases whose infectious material escapes by an easily defended route, perhaps diphtheria alone seriously endangers the ordinary clothing. A protective dress should be worn because the attendant upon a diphtheria patient usually deals somewhat directly with the infectious material.

It seems to me that general practitioners have in most respects allowed the specialists to go far ahead of them in the practical hygiene of daily work. In this matter of proper apparel their tardiness is particularly apparent. Those who pursue such subsidiary occupations as nursing and undertaking are more careful. The singular spectacle of the general practitioner standing, thus negligent of dress, between the sensibly clad surgeon on one hand, and the uniformed nurse on the other, may be partly explained by the excess of consideration which the professional hygienist, when discussing this subject, usually gives to the clement of personal

¹ Read before the American Public Health Association at Indianapolis, October 25, 1900.

safety. This consideration leads to special clothing of monstrous design, frightful to look at, and to wear, as fretful as a boil or a bustle.

To the average patient more or less befuddled by his disease, a gowned, hooded and gloved specter must be somewhat discouraging, suggesting that the uncouth visitor is more careful of himself than of his patient. Certainly the apparition is fearsome rather than heartening.

No costume which disguises the helpful humanity of its wearer will ever commend itself to the common sense of the profession. Any sacrifice of technical detail is justifiable, provided a just balance be maintained between the safety of the public on the one hand, and the welfare of the infected household on the other. If these two considerations are fairly weighed, the attending physician must disregard well-

founded theory and common, though unconfessed, experience in order to determine that he will not protect his clothing.

Most physicians appear to have so determined. While they may try to instruct attendants concerning the avoidance of infection, they exhibit no outward and visible sign of care for themselves as either victims or vehicles of infection. Being without the outward and visible sign, it is, from the layman's viewpoint, reasonable to infer that they lack also the inward grace of antiseptics.

When the rank and file of the profession begin to dress properly for attending infectious cases, they will do so no less for the protection of their business interest than for the sake of personal and public safety. The practice will be certain to receive the stamp of popular approval, and that speedily.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ending January 5, 1901:

Wednesday, January 2—College of Physicians.

Thursday, January 3—Obstetrical Society.

Dr. John M. Swan has been appointed demonstrator of osteology in the University of Pennsylvania.

The German Hospital has received a gift of \$1,000 from the Baldwin Locomotive Company and one of \$100 from Henry Diston and Sons.

Dr. T. Hewson Bradford has just been appointed medical director of the Presbyterian Ministers' Fund, to fill the vacancy caused by the death of Dr. George W. Sparks. This institution was organized in the year 1716 and was incorporated by a charter obtained from the Proprietary Government of Pennsylvania in the year 1759, on the petition of the synod of Philadelphia and, it is believed, is the first body incorporated in our country at the instance of any organized representation of the Presbyterian Church.

Vital Statistics of Philadelphia for the week ended December 22, 1900:

	463	
Total mortality	CASES.	DEATHS.
Inflammation of appendix 1, bladder 1, brain 12, bronchi 12, kidneys 15, heart 1, lungs 64, peritoneum 7, stomach and bowels 11, rectum 1, tonsils 1		126
Lungs—tuberculosis of		65
Heart—diseases of 48, fatty degeneration of 3, neuralgia of 2		53
Marasmus 8, inanition 16, debility 2		26
Paralysis 12, apoplexy 11		23
Uremia 10, Bright's disease 8, diabetes 5		23
Carcinoma of breast 5, rectum 1, stomach 3, uterus 7, multiple sarcoma 1, pelvic sarcoma 1, tumor of brain 2, ovarian 1		21
Convulsions 16, puerperal 1		17
Old age		13
Diphtheria	86	10
Typhoid fever	86	10
Burns and scalds		6
Casualties		6
Brain—dropsy of 1, softening of 5		6
Membranous croup		4
Scarlet fever	67	4
Asthma		3
Liver—cirrhosis of 2, sclerosis of 1		3
Cyanosis		3
Bowels—hemorrhage of 1, obstruction of 2		3
Suicide—carbolic acid 1, hanging 1, shooting 1		3
Teething		3
Aneurysm of aorta 1, alcoholism 1, anemia 1, atheroma 1, drowned 1, erysipelas 1, hemorrhage of stomach 1, umbilical 1, hernia 1, influenza 1, intussusception 1, rheumatism 1, septicemia 2, syphilis 1, tetanus 2, ulceration of stomach 1, unknown Coroner's case 1, whooping-cough 2, knife wounds 1		

NEW YORK.

The Erie County Medical Association as a branch of the New York State Medical Association was organized in Buffalo, December 20, 1900. By-laws were adopted and officers were elected.

The New York Orthopedic Dispensary and Hospital will hold its annual meeting January 4, 1901. Addressess will be made by Bishop Potter and Governor Roosevelt, and the hospital will be open for inspection from 3 until 6 P.M.

Medical Department of the University of Buffalo.—The Alumni Association at their quarterly meeting, held December 21, 1900, listened to a paper on "Bacterial Toxins," by Dr. Victor C. Vaughan, of the University of Michigan, in which he discussed the relation of toxins to the germ producing them, their attenuation and their increase of virulence, the character of the cell-wall, and its permeability by the contained toxins. His paper was a resume of his latest work on these important substances.

An epidemic of measles, mostly confined to children, developed on board the steamship *Trojan Prince* on the voyage from Genoa to New York. On the arrival of the ship, December 20, 48 of the passengers were transferred to North Brother Island for treatment and observation.

A Generous Gift.—The Medical Department of the University of Buffalo is in receipt of a gift of \$50,000 for the purpose of erecting a laboratory to be devoted entirely to research work. The gift is from one of Buffalo's wealthy women, and the laboratory is to be known as the Gratwick Research Laboratory. Ground has been broken and the erection of the building has been commenced. The New York State Cancer Laboratory will be moved into this building from its present quarters in the college, as soon as the building is completed.

Buffalo Academy of Medicine.—The Section of Ophthalmology, O.ology, and Laryngology at the meeting held December 17, 1900, had a paper presented by DR. A. A. HUBBELL on **The etiology and treatment of concomitant strabismus, a reconsideration.** DR. A. G. BENNETT also presented a paper on **The influence of the vertical muscles in the production of asthenopia.** The Section of Pathology at its meeting December 18, 1900, had a paper presented by Dr. A. L. BENEDICT on **Some notes on globulin and albumose as found in urine.** DR. EUGENE WASDIN read a paper on **Acute infection.**

NEW ENGLAND.

A nursery for blind babies has been established in Boston and will be opened on New Year's Day.

Diphtheria Carried by Cats.—The Hartford, Conn., Board of Health has recently ordered all the sick cats in the neighborhood of Park Terrace to be killed, as there are many cases of diphtheria prevailing there, and the health officials decided that the disease was being spread by these animals. A sick cat caught and inspected was found to have diphtheria.

A hospital for tuberculosis is proposed for Providence, R. I. The State Board of Health has lent its support to the movement for its establishment and proposes to induce the General Assembly to vote it the sum of \$200,000 for its establishment and thereafter to provide the means for its continued support. Committees were appointed by the Providence Medical Society and the Rhode Island Medical Society to further the plans of the State Board of Health.

The Cambridge Medical Improvement Association at a recent meeting discussed the "undrained area between Arlington, Somerville, Belmont, and Cambridge." The principal speaker was W. Lyman Underwood, of the Belmont Board of Health. It was voted that the danger to the public health demanded the immediate reclamation of the district in question. United action on the part of the cities and towns interested was urged. A committee was appointed to concur with one already at work, to bring about the desired result.

The Yale Medical School and the General Hospital Society of Connecticut it is reported are about to be drawn into closer union. Negotiations pending for some months between the university and the society have resulted in an agreement by which the former with university funds, is to erect a medical clinical building on the hospital grounds in this city at a cost of \$3,500. The building is in general to be used by Yale Medical School professors and instructors connected with the hospital. The university will pay a small rent for the running expenses of the building.

Yale Medical School.—The following changes in the medical faculty are announced in the Yale University Catalogue recently issued: Dr Otto G. Ramsay, of Baltimore, has succeeded the late Professor James Campbell as professor of obstetrics; Russell H. Chittenden, director of the Sheffield Scientific School, has succeeded Professor Benjamin Moore as professor of physiology; F. S. Hollis has succeeded W. H. Parker as instructor in chemistry, and Dr. Percy D. Littlejohn has taken the place of Dr. W. H. Crowe in the medical clinic. The only changes in the courses of instruc-

tion are the additions of recitations and hospital work in Dr. Robert E. Peck's clinical dispensary work in neurology and a series of six lectures by Dr. Shepherd on "Life Insurance Examinations."—[*Boston Medical and Surgical Journal.*]

WESTERN STATES.

Hog cholera is carrying off hundreds of swine in the region about Zion City, Illinois.

The Stormont Hospital, Topeka, Kan., was partially destroyed by fire December 20; the estimated loss is over \$10,000.

A Convict Farm.—The Mississippi State Board of Control has purchased 13,000 acres of land in Sunflower County on which to establish a convict farm.

Agatha Hospital has lately been opened in Clinton, Iowa. It is a charitable institution and \$20,000 was raised by subscription to build the handsome structure.

Pneumonia is reported as epidemic in Chicago, but, like the influenza which has prevailed for the past 2 weeks, is of a milder type compared with epidemics of former years.

Diphtheria is prevalent in Ocean View, California, more than 30 children being affected, and during the past month 30 deaths have resulted from it. There is general complaint of the unsanitary conditions of the place.

The St. Louis District Medical Society at a late meeting appointed a committee to frame a proposed law for the regulation of the practice of medicine in the State, and also regulating the giving of diplomas by unauthorized medical colleges. They will strive to have this legislation enacted at the approaching session of the Legislature.

Evanston Hospital.—Plans for additions and improvements to this hospital, which will entail an outlay of nearly \$50,000, have been completed by a committee who have made thorough investigation in this country and Europe to find the best methods of constructing buildings for hospital uses. The plans include the erection of the new Herman D. Cable memorial building.

Disinfection of Foreign Fruit.—Orders have been issued by the assistant-surgeon in charge of the Columbia River quarantine station at Astoria to the importers and shippers of Portland and to the Northern Pacific Steamship Company relative to the disinfection of fresh products from China and Japan. The following articles require disinfection before they can be admitted, viz., water chestnuts, salt eggs packed in loam, yams, lily bulbs, and similar fresh fruit products from China and Japan, unless the same are accompanied by a certificate from the Marine-Hospital Service officer at the port of departure, stating that these articles do not come from a district where plague is epidemic, and are free from infection.

The plague reports officially made by Dr. Kinyoun, federal quarantine officer in San Francisco, are the subject of complaint by the merchants and shippers generally, who charge him with injuring the commerce of that port by unjustified reports of bubonic plague sent to Washington, and a suit has been filed against him in the United States Circuit Court for alleged neglect in the exercise of his official duties to issue and deliver to the Occidental and Oriental Steamship Company some pratique that would enable them to deliver to the complainant Wong Chung, a Chinese, merchant goods to the amount of \$2,000, which the steamship company hold but threaten to throw overboard.

Trichinosis has developed in 4 members of a Milwaukee family, who have indulged freely for 3 weeks in uncooked sausage, made partly from 95 pounds of pork butts obtained from a large packing house in that city, but which was not sold as inspected meat. When ill symptoms became manifest, the family had the sausage inspected, and it was found to be full of *Trichina spiralis*. The United States Government requires an examination of all hogs and cattle before they are killed, to see that they are healthy, and after they are slaughtered a postmortem examination is made, but orders no microscopic examination of meat for home consumption,

the microscopic tests being made only of meat that is to be exported to countries where the eating of raw meat is a common practice. Thus, as a matter of fact, the foreigner is assured of an immunity against trichina that is not enjoyed by meat-eaters in this country.

Bubonic Plague in San Francisco.—W. F. Blunt, the Texas State Health Officer, reported officially, December 20, to Governor Sayres on the plague condition at San Francisco as follows:

"The plague was first officially reported from Bombay in April, 1898, since which time it has made rapid progress. It reached San Francisco last March. It has also reached both coasts of South America, and has appeared in Europe at Oporto, Hamburg, Glasgow, and London. This has made it necessary to maintain an interstate quarantine against that city from May 29 of the present year until now, and I regret to say that the disease continues to spread there.

"Dr. J. J. Kinyoun, Federal quarantine officer at San Francisco, reports officially: 'I would state that it is my belief that the area of infection is gradually growing wider, so that now there are only three blocks of the Chinese quarter proper in which there has not occurred since March last a case of plague. The conditions which will obtain in the next six months will be, in my opinion, conducive to a further spread of the disease. I believe other cases occurring in San Francisco are being reported under another name.'

"On account of the strenuous efforts of the press and certain other interests in San Francisco to suppress the fact of the existence of the disease there, much confusion has existed in the public mind, and the policy of quarantining against that city has been much criticised. I have acted on the fullest and most satisfactory evidence. To this end I have visited San Francisco twice and fully investigated the facts. Briefly stated, they are as follows:

"Twenty-two cases have been officially reported by the City Board of Health of San Francisco, the first case occurring March 6, 1900. With the exception of four cases, they have all been found after death. All but two occurred in the Chinese quarter, and all save three were Chinese. Many of them had been treated during their illness, and death-certificates given by the attending physician for other diseases. Diagnosis was made by postmortem and bacteriologic methods, the most exact methods known to medical science. This diagnosis has been concurred in by every competent authority that has made an examination, among whom I will mention Drs. J. J. Kinyoun, Roesean, Geddings, Kerr, Lumsden, Gasaway, and Agnes Walker, of the Marine-Hospital service; Dr. Kellogg, pathologist of the Board of Health of San Francisco; Profs. Montgomery, Kerr, Ryfkogel and Taylor, of the University."

SOUTHERN STATES.

The Sewanee Medical School, in Tennessee, has held recently its ninth annual commencement and completed its most successful year. The graduating class numbered 101 men, and the Sewanee School of Pharmacy graduated 40.

The University College of Medicine of Richmond, at a meeting of the Board of Trustees, December 21, 1900, elected Dr. J. A. Hodge as president. He has held successively the positions of professor of anatomy, dean, and proctor, and now succeeds the late Dr. Hunter McGuire.

MISCELLANY.

Sanatorium for Manila.—It is reported that the establishment of a sanatorium convenient to Manila is under consideration at Washington and the selected site is Beago de la Trinidad, about 4,700 feet above sea level.

Sick Soldiers from the Philippines.—More than 1,000 sick soldiers are on their way home from the Philippines. The *Grant* and *Sherman* are now en route with 650 men, and the *Sheridan* with 500 more. This rush will tax the general hospital at the Presidio to its utmost capacity. The convalescents will be mustered out as soon as possible after they arrive, and if the 867 available beds at the hospital become overcrowded a tented annex will be built to accommodate the overflow.

Hospital Ship "Maine" is expected to arrive at Southampton, England, January 10, with 18 sick men on board. After consultation with the naval and military authorities in China, the Government has decided that the *Maine* will not be further needed, so, on her arrival here, the ladies' committee will wind up the business and hand over the ship to its owners.

Dead Soldiers from the East.—It is stated at the War Department that the transport *Grant*, which is due at San Francisco about January 1, brings the remains of 398 officers, soldiers, and civilian employees of the War Department, who died in Hawaii, China, or the Philippines, and that there are 12 dead on the transport *Sherman*, which is due at San Francisco on January 12.

The Sanitary Condition of Cuba.—General Leonard Wood has written a letter to the Adjutant-General of the Army aiming to correct the prevailing public opinion in the United States in regard to the sanitary situation now existing in Cuba, and states that the whole island is free from epidemic or contagious disease with the sole exception of Havana, where there still remain a few cases of yellow fever, though not enough to receive serious consideration. "The total death-rate from all causes in the city of Havana for the month of November was the lowest of any month without regard to season, for 10 years. Inasmuch as apprehension arising out of the yellow-fever situation of the past summer still remains, it may be advisable to give this subject general publication, in order that full commercial and other relations with the island will be resumed."

Starvation in Porto Rico.—The report of A. D. Williams, assistant surgeon of the United States Army, depicts a sorrowful condition of the people in Porto Rico, where he has been detailed to make observation on a march with soldiers across the island. The most appalling conditions were found at Adjuntas, the men, women, and children swollen, bloated, diseased, and emaciated, whose pinched and haggard features appeared weighted with the sorrows of years. The average death-rate of about 52 each week was ascribed by the physician to chronic starvation. Dr. Williams declares that with 14 patients in the hospital at this place and 3 nurses, the municipal authorities allow the steward to draw only \$1 a day in municipal stamps for the subsistence and care of the patients, and that the steward can realize only 50 cents for his stamps, and with that amount daily he has to provide the scanty hospital food.

Obituary.—EPHRAIM INGALIS, of Chicago, December 18, aged 77.—GEORGE H. ELLIOTT, of New York, December 17, aged 55.—CHARLES SABIN TAFT, of Mount Vernon, New York, December 18, aged 65.—ABSAALOM J. KALB, of Quincy, Ill., December 16, aged 83.—LEROY J. BROOKS, of Norwich, New York, December 12.—RICHARD A. WISE, of Williamsburg, Va., December 21, aged 57.—WILLIAM P. CALWELL, of White Sulphur Springs, Va., December 8, aged 62.—CASSIUS C. DAVIDSON, of Akron, Ohio, December 9, aged 50.—HENRY T. WOODRUFF, of Harvard, Ill., December 17, aged 61.—WILLIAM H. DAUGHTRY, of Sunbeam, Va., December 14.—A. B. KARTERMAN, of Hepler, Pa.—WINONA JENNINGS, of Cincinnati, December 13.—W. G. BIGELOW, of Stormstown, Pa., November 28, aged 87.—GEORGE C. ROBERTS, of Chattanooga, Tenn., December 3, aged 43.—ORLANDO J. HARRAN, of West Beatrice, Neb., December 10, aged 77.—J. S. ZUKOSKIE, of Ensley, Mich., November 14.—FREDERICK A. HOPKINS, of Montreal, December 1, aged 34.—SAMUEL C. TISDALE, of Port Lavaca, Tex., December 4.—KIRK C. MCKINNEY, of El Paso, Tex., December 8, aged 29.—FRANK S. HARKER, of Richmond, Va., December 8, aged 42.—J. PERRIN JOHNSON, of Sioux City, December 9, aged 72.—JAMES H. MCDANIEL, of Centreville, Tex., November 26.—ADOLF F. KRAUSE, at Bowdle, S. D., December 5.—RANDOLPH N. HOWARD, of Carrington, N. D., December 7.—P. L. HUDSON, of Cochran, Ga., November 30.—JOHN WHEELER, of Pittsfield, N. H., December 20, aged 72.—A. J. SMITH, of Wabash, Ind., December 22, aged 70.—BYRON N. TAYLOR, of Menominee, Mich., December 22, aged 48.—THOMAS O. WALTON, of Annapolis, December 21.—N. M. BURKHOLDER, of Harrisburg, Va., December 8, aged 59.—JAMES F. SMITH, of New Brighton, New York, December 11, aged 24.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended December 21, 1900:

SMALLPOX—UNITED STATES.

Smallpox cases in New York, it is reported, continue to develop at the rate of 3 or 4 a day in localities widely remote from one another, and the hope of stamping it out seems to lie in a continuance of the general movement for vaccination. The health officials say that since the year 1875, when this city suffered from a smallpox scourge that took 1,280 lives, the epidemic has visited New York in waves, the crests of which have been 6 or 7 years apart, and that its increase has always been the accompaniment of a decrease in vaccination, and vice versa. The city now seems to be nearing the crest of the fourth wave since 1872, if it has not already attained it. In Indiana 100 new cases are reported, and it is estimated that there are now 256 cases in the State, 60 of which are in Allen County. In Kansas City the disease is breaking out in unexpected places, and 10 new cases, all among negroes, have been removed to St. George's Hospital, which is rapidly filling up. An appropriation of \$3,000 has been made by the City Council for a smallpox hospital, but there is a dispute as to its location, the people in the

neighborhood of the site selected (East Bottoms), refuse to be subjected to the risk of infection, and threaten to defend their district by force of arms. A student in the Milwaukee Medical College, and a medical student in the University of Michigan have developed smallpox, which created a furor of apprehension in the respective places. It is reported prevalent in Washington among the Indians on the Coeur S. Alene reservation, where in some families the disease has developed into the acute stage. Of the numerous cases developed in Travis County, Texas, there has been but one fatal case among the negroes. At the railroad camp at Pinto, Alleghany County, Md., 14 suspected cases besides 5 genuine cases are reported. A colored physician remains on the ground to take charge of them, and an armed guard has been detailed to prevent the spread of the disease. A report that 60 negroes, who had been exposed to infection, were on their way to Clarksburg, W. Va., caused the local company of the National Guards to be called out and stationed on the roads commanding that city to hold up all negroes until they could prove themselves not infected.

Changes in the Medical Corps of the U. S. Army for the week ended December 22, 1900:

WALSH, Captain PHILIP G., assistant surgeon, having been honorably discharged from the Volunteer service as major and surgeon of the Thirty-ninth Infantry, U. S. Volunteers, is relieved from duty in the division of the Philippines and will proceed to San Francisco, Cal., reporting by telegraph to the Surgeon-General of the Army.

RHOADS, First Lieutenant THOMAS L., assistant surgeon, is relieved from duty at his present station and will accompany the Twenty-first Infantry into the department of Southern Luzon.

SHAW, Captain HENRY A., assistant surgeon, will report to the commanding general, department of Northern Luzon, for assignment to duty.

GILHULEY, JOHN J., acting assistant surgeon, will proceed to his home, Bridgeport, Conn., from where he will report to the Surgeon-General of the Army for annulment of contract.

HALL, ANDY, acting assistant surgeon, will proceed to his home, Mount Vernon, Ill., where he will report to the Surgeon-General of the Army for annulment of contract.

FINKELSTONE, HYMAN, acting assistant surgeon, will proceed to his home, New York City, from where he will report by letter to the Surgeon-General of the Army for annulment of contract.

DRIVER, GERRY S., acting assistant surgeon, will proceed to his home, Chicago, Ill., from where he will report by letter to the Surgeon-General of the Army for annulment of contract.

BYRNE, JOHN G., acting assistant surgeon, will proceed to his home, Chicago, Ill., from where he will report to the Surgeon-General of the Army for annulment of contract.

DISNEY, F. A. E., acting assistant surgeon, will proceed to his home, Waterbury, Conn., from where he will report by letter to the Surgeon-General of the Army for annulment of contract.

BISPHAM, First Lieutenant W. N., assistant surgeon, is granted leave of absence for 1 month, with permission to go beyond the limits of the department of Cuba.

MCCALL, JAMES H., acting assistant surgeon, is relieved from duty at Fort Schuyler, to take effect upon the expiration of the leave of absence granted him November 6, and will then proceed to San Francisco, Cal., and report to the commanding general, department of California for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

WILSON, COMPTON, acting assistant surgeon, upon the expiration of the leave of absence granted him December 6, will proceed from London, Ontario, Canada, to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

FLETCHER, JR., RICHARD M., acting assistant surgeon, extension of leave of absence granted November 19 is further extended 1 month.

ANDREWS, CHARLES H., acting assistant surgeon, leave of absence granted him on December 3 is extended 1 month.

COWPER, HAROLD W., acting assistant surgeon, is relieved from duty at Fort Ontario, to take effect when his services shall be no longer needed at that post, and will then proceed to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

SARGENT, ERLE H., acting assistant surgeon, is relieved from duty at Fort Casey and will proceed to Camp William H. Osborne, Idaho, to relieve Acting Assistant Surgeon Jesse P. Truax.

TRUAX, JESSE P., acting assistant surgeon, will proceed to Fort Casey for duty.

CARR, Major LAWRENCE C., surgeon, is granted leave of absence for 2 months.

BACON, JOHN E., acting assistant surgeon, is relieved from duty at Fort Duchesne and will proceed to Fort Grant and report by telegraph to the Surgeon-General of the Army for annulment of contract.

GOULDING, TIMOTHY F., acting assistant surgeon, will upon the expiration of his present leave of absence, proceed from Boston, Mass., to San Francisco, Cal., for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

Changes in the U. S. Marine-Hospital Service, for the week ended December 20, 1900:

PERVIANCK, GEORGE, surgeon, to report at Washington, D. C., for temporary duty. December 14.

SAWTELLE, H. W., surgeon, granted leave of absence for 30 days from January 20, 1901. December 18.

WHITE, J. H., surgeon, bureau letter of October 11, 1900, granting leave of absence for 30 days, amended so that said leave shall be for 12 days only. December 18.

CARRINGTON, P. M., surgeon, granted leave of absence for 30 days on account of sickness. December 18.

CORR, J. O., passed assistant surgeon, relieved from command of service at Fort Stanton, N. M., and directed to report to medical officer in command for duty. December 20.

ROSENAU, M. J., passed assistant surgeon, upon completion of duty at Paris, France, to rejoin station as director of hygienic laboratory, Washington, D. C. December 19.

McMULLEN, JOHN, assistant surgeon, relieved from duty at Tortugas Quarantine, and directed to proceed to Savannah, Ga., quarantine station for temporary duty. December 15.

KORN, W. A., assistant surgeon, granted leave of absence for 7 days from December 24. December 17.

OLSEN, E. T., junior hospital steward, granted leave of absence for 10 days from December 22. December 7.

APPOINTMENT.

FRASER, A. C., of Wisconsin, appointed acting assistant surgeon, fort duty at the port of Manitowoc, Wisconsin. December 17.

Changes in the Medical Corps of the U. S. Navy, for the week ended December 22, 1900.

LEBRETT, R. E., assistant surgeon, detached from the "Constellation" and to the "Monongahela."

MURPHY, J. A., assistant surgeon, detached from the "Solace" and to the "Don Juan de Austria."

STIEPP, JACOB, assistant surgeon, detached from the "Solace" and to the Cavite Naval Station.

STONE, M. V., assistant surgeon, detached from the "Yosemite" and to the "Isla de Luzon."

THOMPSON, J. C., assistant surgeon, detached from the Naval Hospital Cavite, P. I., and to the "Solace."

Cancer of the Esophagus with Perforation into the Left Pleura.—Friedenwald (*The Journal of the Alumni Association of the College of Physicians and Surgeons*, Baltimore, October, 1900), reports a case of carcinoma of the esophagus occurring in a woman of 31. Difficulty in deglutition was experienced in July. The condition gradually grew worse till the following December, when operation was performed. The stomach was opened and graduated bougies were forced past the esophageal stricture which was 10 cm. from the cardiac end; when the second bougie was passed, something was felt to give way. The patient did well for 4 days, when pain in the left side of the chest and a rise of temperature developed. An effusion was found in the left pleura, and tapping and subsequent resection of a rib revealed a pyothorax. A limited autopsy showed the esophagus was perforated, and septic material had passed into the pleural cavity, setting up the secondary condition. [A.B.C.]

Indications for Bleeding.—Hayem (*Treatment*, November, 1900) stated at the recent Congress of Medicine that the cases in which bleeding is indicated are those in which life is immediately endangered, either by circulatory detanglement or by toxemia, in such conditions as the following: In acute edema of the lungs, particularly in diseases of the large vessels or of the kidneys; certain cases of pneumonia of edematous or simply congestive type; certain mechanical troubles of the circulation, due to disease of the heart or great vessels, particularly in high arterial tension, but also in some cases of evident asystole; congestive and hemorrhagic forms of acute nephritis; cerebral congestion, and hemorrhage in the subjects of high arterial tension; recent acute uremia; puerperal eclampsia; intoxication of the blood by certain gases, notably by carbonic oxid.

Foreign News and Notes.

GREAT BRITAIN.

Street Cries.—The Middlesex County Council has proclaimed as a nuisance the cries of street hawkers and has already begun prosecutions. The law aims to protect quiet people who need rest, as well as invalids.

Two deaths from septicemia following tooth extraction have occurred at Bow and Manchester. In both cases the operators were unqualified dentists, and it is believed the infection was due to the use of dirty instruments.

Dr. Anton Baron von Eiselsberg, professor of surgery in Königsberg, has been recommended by the Professoren-Collegium as the successor of the late Professor Albert in the chair of surgery in the University of Vienna.—[*British Medical Journal*]

A memorial to the late Professor A. W. Hughes has taken the form of a medal to be awarded annually in the medical school of the University College, Cardiff, and a fund to endow the anatomical museum which owes its origin to a gift from Professor Hughes.

Bacteriologic examinations by the Health Committee of Edinburgh have been begun. They include sputum, urine, milk, blood for typhoid, and throat cultures. Unnecessary alarm has been caused by reports of an epidemic of diphtheria, which is not warranted by the facts.

Women Health Officers.—A "Lady Sanitary Officer and Health Inspector" has been appointed in Southwark. The homes of the poor are to be visited and efforts made to improve the sanitary conditions with special reference to the care of children. The women are also to be instructed in domestic details.

Homes for the London Poor.—At the recent annual conference of the National Union of Conservative Associations, Lord Salisbury, commenting on the remarkable change of London from a Radical to a Tory stronghold, remarked that the only radicalism remaining was found where the burning question was the housing of the poor. The Conservatives, he added, could not more surely maintain their hold on the public than by devoting their whole power to removing this scandal of civilization—the suffering many working people had to undergo from the pitiable accommodations—and providing adequate, healthful habitations for the poor.

The Vermiform Appendix Not a Vestigial Structure.—Dr. R. J. A. Berry, of Edinburgh, from investigations regarding the comparative anatomy of the appendix, finds that the homolog in animals is the cecum, which contains much lymphoid tissue. His conclusions are; 1. That lymphoid tissue is the characteristic feature of the cecal apex (the vermiform appendix of man was therefore represented in the vertebrate kingdom by a mass of lymphoid tissue situated usually at the cecal apex). 2. That as the vertebrate scale ascended this lymphoid tissue tended to be collected together into a specially differentiated part of the intestinal canal—the vermiform appendix. 3. That the vermiform appendix is therefore not a vestigial structure, but a specialized part of the alimentary canal.

Working-Class Metabolism.—Experiments dealing with the sufficiency of diets of the poor have recently been made in Edinburgh. Working people were divided into 3 groups: (1) Families with an irregular income under 20s. a week; (2) those in receipt of 22s. a week regularly; (3) those earning 30s. or over per week. Articles of diet purchased each week by classes 1 and 2 were analyzed and showed conclusively that either in actual amount or in quality they were incapable of supplying the body with sufficient nutriment. In the production of energy and heat the foodstuffs consumed were 6.8% below the normal, and as much as 15.7% below that needed for the growth and repair of the body. The families in better circumstances maintained metabolic equilibrium fairly well.

An Important "Skim Milk" Case.—A dairyman at Glasgow has been prosecuted for selling as "skim milk" milk which had been separated by mechanical means until only .28% of fat remained. The prosecution claimed that if the fat was below 1% the substance was not of the "nature, substance, and quality of skim milk." The dealer refused to accept this standard and claimed the right to remove the entire fat and still sell the remainder as skim milk. The decision went against the prosecution; the opinion being that "the article of commerce known as skim milk equally answers that description whether the fat in it is 2% or 1% or nothing."

Arsenical Beer.—Inquiry shows that many cases of poisoning date their symptoms as far back as last Easter, though some are now seeking medical aid for the first time. Although Manchester furnishes the most cases the malady has extended over a wide area, some of the worse cases being found in rural districts. As a rule women suffer more severely than men. Persons who use only 1 to 2 pints of beer or stout a day have been badly affected. Psychical derangements have been well marked. Loss of memory is quite common. The epidemic in Liverpool is subsiding. It is likely that a large number of suits for damages will be instituted by relatives of deceased persons. Who are the responsible parties is not so easy to decide. The *Medical Press* observes: "One aspect of the Manchester outbreak is worthy of special attention—namely, the fact that the momentous discovery of this obscure and baffling source of peripheral neuritis was due to skilled medical observation rather than to pure laboratory work."

Isolation of Tuberculosis at Schools.—A pronouncement has been made by the English Board of Education, which, for the present at all events, contravenes the assertion of the ultrasanitarians that, to be effective, isolation of tuberculous cases must be undertaken by the sanitary authority from the first day on which the disease declares itself to the last, when the patient dies or is finally cured. The clerk of the Kingston-on-Thames Union addressed the following letter to the Board of Education: "My School Attendance Committee is much exercised as to what their statutory duties are where children of school age with a tendency to consumption are kept back from school on that account. My committee view with serious alarm compulsory attendance at school of such children, however slightly they may show symptoms of this disease, and I am to ask whether, in the opinion of my Lords of the Privy Council, the several authorities would be justified in creating separate classes for consumptive children to attend, if sufficient were found in the several districts to justify the outlay." In reply, the Department stated: "The Board of Education are advised that a tendency to consumption is itself no bar to attendance at school. But a child suffering from actually developed phthisis ought to stay away as fit only for medical treatment and as infectious and dangerous to the other scholars. In doubtful cases, when no medical certificate is forthcoming from the home, your committee should take steps to obtain one. Special classes for consumptive children do not appear to be desirable."—[*Medical Press*.]

CONTINENTAL EUROPE.

Richey's Cure for Tuberculosis, which consists of an exclusive raw meat diet, it is stated has been tried for 3 months in an institution opened in Belgium for that purpose, and the experiment abandoned as totally inefficient.

A plague laboratory has been established in the Hygienic Institute of Munich, under the direction of the head of the Institute, Professor Hans Buchner, who has named Dr. Hahn his deputy. The laboratory is intended for the examination and diagnosis of suspicious cases of plague.—[*British Medical Journal*.]

Physicians in Germany.—Official statistics recently published exhibit the overcrowding of the medical profession in the large cities and the necessity for the decree to lengthen the term of medical study as a remedy for the overproduction of physicians. Berlin has 1 physician to every 798 of population; Breslau, 1 to every 775; Halle, 1 to every 735; and Königsberg 1 to every 681.

A curious case of loss of memory is reported from Worms. A small landowner was struck by lightning while ploughing, the flash passing through his hat, leaving a hole as large as a fist, then down his neck and through the plough-handle into the ground. The victim, who was ill for several days, finally recovered, but he has entirely lost his memory.

Molten Wood.—The reduction of wood to a molten condition by means of fractional distillation and high pressure to prevent the escape of developing gases—is reported to have been effected by M. de Gall, inspector of forests at Lemur, France. The mass when cool assumes the character of coal, yet without showing any trace of organic structure. It is hard, susceptible to shaping and polish, impervious to water and acids and a complete electrical nonconductor.

Remedy for a Decreasing Birth-Rate.—A bill aiming to provide a remedy for the threatened depopulation of France has been introduced into the French Senate imposing a tax upon the unmarried of both sexes after they reach the age of 30, and upon childless couples who have been married 5 years, the tax to be maintained until a child is born to them. Published official statistics show also a continued decrease in the Berlin birth-rate, which is now only 29 in 1,000.

German Wine Law.—A bill revising the wine law of Germany has just been published which prohibits the addition of sugar water to partly pressed grapes in making wine and the use of decoctions from dried fruits, as well as acids and essences for securing an artificial bouquet. Officials charged with the duty of inspection are authorized to enter vintage rooms, cellars, and stores to examine books and to take samples. The bill provides penalties not to exceed 6 months' imprisonment or a fine of 3,000 marks.

Prevention of Malaria in Italy.—It is said that Prof. Celli, who is a member of the Italian Parliament, will introduce drastic measures for the suppression of malaria in Italy. He would make punishable by law the neglect of landowners and all employers of labor to provide in malarial districts every means of fighting the fever. Boselli and Sonnino have proposed that the Minister of Finance purchase pure quinin and sell it to the public at a slight advance over cost. The profit would be applied to the extermination of malaria.

Surgical Asepsis.—Prof. Terrier, at the Pitié Hospital in Paris, constantly aims to simplify methods of asepsis. For washing the hands or cleaning instruments during an operation sterilized water or saline solution is used. The sodium chlorid is made sterile by melting it in a crucible. The hands are dipped in the solution very often and wiped with a sterile compress. It has been shown that if the hands are not washed during an operation, the sweat glands render them septic. Alcohol and ether are never used. The patient's skin is washed with soap and boiled water, then with saline solution and dried. Silk is used for sutures exclusively, catgut only exceptionally.

Discovery of a Statue of Esculapius in the Roman Forum.—Among the recent interesting finds in the Roman Forum is a statue of Esculapius. It was lying face downwards under the central niche of the large arched space surrounding the Well of Juturna, which has lately been excavated under the direction of Professor Boni. The head of the figure and the middle of the right arm are wanting, but the other parts are well preserved. It represents the god, with a *volumen* (or roll of paper or parchment on a stick) in the left hand, leaning on his staff, round which is coiled the serpent, the symbol of prudence and renovation. Close to the staff is a child, supposed to be Camillus or Telesphorus, the genius of recovery, in the act of bringing the offering of a cock in his left hand and holding in his right hand a small knife with a pointed blade. The well enjoyed a reputation for the salubrity of its water, and this fact explains, no doubt, the presence in its precincts of the statue of the god of medicine, under whose special protection such wells were placed. The worship of Esculapius is said to have been introduced into Rome from Epidaurus about 293 B. C., but this statue, which is of indifferent workmanship, belongs to a much later period, probably the first or second century of the Christian Era.—[*The Lancet*.]

Adulteration of Food in Switzerland.—A communication to the State Department from the American Consul, M. De Boise, at St. Gall, Switzerland, declares the adulteration of food general in Europe and in Switzerland legislation has had to be made against it. The chocolate, the consumption of which the slot machines have increased, is adulterated with mutton-tallow, sawdust and potato meal. The chief ingredients of honey are syrup, meal and cornstarch, Swiss cheese is mixed with potatoes ground to a powder; butter is adulterated with carrot juice. Bread, which furnishes 70% of the nourishment of the people of the Swiss republic, is mixed with potato meal and the dough is soaked heavily with water to add to the weight of each loaf. With coffee, tanbark, sawdust, stove rust and chicory are mixed; and as adulterants for tea, linden, sage and strawberry leaves are used. It is proved by analysis that in beer the following ingredients are added as substitutes for malt and hops: Potash, vitriol of iron, alum, licorice, linseed, solution of tartar, poppy heads, guinea grains, chamomile, pine sprouts, chicory, henbane and wild cherries. Some of the wine which is freely consumed, he declares has never contained a drop of grape juice since potato syrup dissolved in rain water makes a salable beverage and the desired color and bouquet are obtained by mixing wine acids with cream of tartar.

MISCELLANY.

The British Pharmacopoeia has been increased by the Indian and Colonial addendums. It contains 54 drugs and 65 preparations and includes drugs which are specially prepared in these places or are substitutes for drugs which would not bear transportation.

Obituary.—JOHN SMITH, of Plumstead, England, December 6, aged 59.—ALEXANDER DEAS DAVIDSON, of Swansea, December 7, aged 51.—GEORGE HUTCHINSON MILNES, of Derby, December 3.—J. W. HESTER, of Newcastle, December 3, aged 35.—EBERHARD REUSCHIEL, of Eschenbach, December 2, aged 51.—JAMES IRVING, of Christchurch, New Zealand, October 26, aged 61.—HENRY GREENWOOD RAWDON, of Liverpool, December 4, aged 64.—ALBERT ERNEST ELLIOTT, of Middelburg, South Africa, December 1.—ROGER EDWARDS, of Colwyn Bay, December 20, aged 60.—FREDERICK EDMUND HUBBARD, of Diss, Norfolk, November 25, aged 42.—BERNHARD SPINOLA, of Berlin, aged 64.

Excision of the Knee-joint.—Primrose (*The Montreal Medical Journal*, November, 1900) says we are often incapable of determining beforehand the amount of involvement of the tuberculous knee joint, and consequently whether excision will be necessary; therefore we should employ that method which will open up for inspection and still stop short of excision if esteemed best. The ordinary methods of opening up the joint are referred to, and then the author describes and advocates the method of Kocher of Bern. The minute details of the method are too lengthy for abstract, but the essential details consist of an incision which starts over the vastus externus, a hand's breadth above the patella, and passes at first perpendicularly downward upon the outer side of the patella, separated from that bone by 2 fingers' breadth; below the patella it is carried with a slight curve inward and ends on the inner surface of the tibia, having passed below the tibial tubercle. The incision is carried to the bone throughout, and by means of a chisel the tibial tubercle, with the periosteum and attached ligamentum patellae, is separated and pushed toward the inner side. This permits the joint to be opened and arthroctomy done if necessary. The author is of opinion that this possesses distinct advantages over the ordinary V-shaped incision which severs the ligamentum patellae—one of which is that in children the epiphyses are more readily preserved from danger. He has not seen this method described in the English journals. It has been employed by him in 2 cases with good results. [A.B.C.]

1.—The article is a summary of the recent researches concerning the **parasitology of malaria**. [J.M.S.]

2.—In the treatment of insomnia hypnotics should be given in exceptional cases only. The physician should rely, whenever possible, upon a judicious employment of some of the nonmedicinal helpers of sleep. Although, in the more severe forms of psychic insomnia he must often secure sleep at once by the action of some efficient hypnotic. Sawyer prefers opium or chloral for this purpose. An overworked man or woman must never be permitted to go on with their overwork and must habitually secure sleep by the use of chloral or any other hypnotic. Potassium bromid is by far the best hypnotic in well nourished patients and in the slighter cases generally. In many cases of chronic wakefulness the patient is distinctly anemic and the insomnia cannot be cured unless the anemia is first relieved. A "nightcap" of toddy gives rest and sleep to the worried brain of feeble persons whose blood is poor. Daily bodily exercise in the open air and sunshine, but always short of great fatigue, is often an efficient means of securing sleep. [J.M.S.]

3.—In the differential diagnosis of **peripheral neuritis due to arsenic** rather than to alcohol the following features are of importance: 1. Hyperesthesia of the skin and muscles, which, although common in alcoholic neuritis, is more constant and generally more severe in the cases due to arsenic. 2. Erythromelalgia. The vasomotor phenomena that characterize the condition known by this name, while only occasionally present in alcoholic cases, have been conspicuous features in the present epidemic. 3. Ataxia is rare in cases of alcoholic neuritis, and therefore, Bury has been much struck by its comparative frequency in the present series of cases. In the treatment the first essential is to find out the cause and to remove it. In all except the slightest cases rest in bed is advisable, and the severest cases require a water bed. On no account must the nurse attempt to massage the limbs in the first stage of the disease. For the relief of tender nerves and muscles there is nothing better than warm fomentations. In the early stages of neuritis, sodium salicylate and potassium iodid, either alone or in combination, appear to be of service. Neuralgic pains may be relieved by the administration of antipyrin, phenacetin, or exalgin; but when the suffering is very great the hypodermic injection of morphin becomes necessary. Let it be particularly noted that in the acute stage atrychnin must not be given. Of far greater importance than drugs is the regular and careful administration of nourishment, in the forms of boiled milk, beef tea, beef extracts, soups, and broths.

When the acute symptoms have subsided, but not before, recourse may be had to massage, electricity, and tonic treatment. Of all drugs that may be regarded as tending to the restitution of the paralyzed parts, atrychnin is unquestionably the most valuable, and it is better to administer it hypodermically than by the mouth. It is advisable to begin with a small dose, say $\frac{1}{16}$ grain, and then gradually to increase the quantity. [J.M.S.]

4.—Moynihan divides the **chronic inflammatory process** in or near the **stomach** that may require surgical interference into the following classes: 1. Temporary intermittent narrowing of the pylorus reflex in character, the result of muscular spasm. This spasmodic contraction is largely or entirely dependent upon chronic ulcer of some portion of the stomach and sometimes resembles a tumor, the cause of which is difficult to determine. After gastroenterostomy it usually disappears, owing no doubt to the rest and subsidence of the hyperacidity. 2. Circumscribed or annular fibrous constriction at or near the pylorus, and it is in this condition that pyloroplasty is attended with its best results. 3. Diffused cicatricial induration at or near the pylorus or the first portion of the duodenum, and in these cases the inflammatory mass often resembles some malignant tumor, and when the ulcer has been healed it breaks down on the most trivial provocation. This condition is best dealt with by a gastroenterostomy. 4. Cicatricial contraction and induration with adhesions between pylorus, duodenum, abdominal wall, liver, gallbladder, etc., are the signs of deep ulcers, where perforation has been threatening. 5. Cicatricial contraction and induration at the site of an ulcer situated in the body of the stomach gives rise to the condition known as "hour-glass contraction." This he again divides. *a* When the ulcer is situated near the middle, and causes a constriction of the organ as if a tape had been tied around it. *b*. When the ulcer is on the anterior surface and adhesions to the abdominal wall cause it to dilate and give it the appearance of an hour-glass. The spot where the adhesion forms causes it to be very tender, and the rigidity of the muscles is often mistaken for a tumor. 6. The last division, includes adhesions external to, and primarily independent of the stomach and duodenum, originating in inflammatory conditions of the gallbladder, bile-ducts, etc., or rarely traumatism. In the surgical treatment of the various conditions, the following procedures are carried out: (1) Pyloroplasty or gastroplasty; (2) gastroenterostomy; (3) pylorotomy; and (4) gastrotomy. Pyloroplasty is of limited use, but in selected cases it serves well, but the scar of the ulcer must be small and sharply defined in width as well as being soft and supple, the incision must be carried into healthy tissue and there must be no adhesions even of the most trivial kind. In performing gastroenterostomy he has used the Murphy button, LaPlace's forceps and sutures; the last he prefers, and believes the best results can be obtained by this method by experienced operators. Pylorotomy is rarely ever required, and in cases of malignancy, when the diagnosis has been firmly established, the disease is too widespread for this operation. The regurgitation of bile and pancreatic secretion into the stomach after these operations does not affect the general health, nor cause any local disturbance. [W.S.N.]

5.—Martin and Pollard report a case of **gastroenterostomy** in a young woman suffering from pyloric stenosis of a nonmalignant character, but there was also a second ulcer in the middle of the stomach which caused an hour-glass constriction. The opening made by the operation was in the second compartment, and as sufficient nourishment could not pass the first obstruction, death resulted from exhaustion. [W.S.N.]

6.—In **pulmonary tuberculosis** pyrexia may be absent and this may be a favorable **prognostic sign**, but it is not always so. If with absence of pyrexia there be extreme general weakness and bacilli in the sputum the condition is grave. The higher the pyrexia the worse the prognosis in the first stage of the disease. A morning temperature that is always above normal is unfavorable, whatever be the evening temperature. General weakness is unfavorable, but especially cardiac and vasomotor weakness. Attacks beginning with digestive disturbances as the only sign generally do badly. Hemoptysis in the first stage need not cause great alarm, although repeated copious hemoptysis increases the gravity of the case. One large hemoptysis with pyrexia

carries with it a serious prognosis if the diagnosis of tuberculosis be fully established. In the second stage of the disease, echoing rales indicate softening of inflammatory tissue. If the disease extends by contiguity of tissue, when the lesion has passed the boundaries of the lobe in which it was first developed, the prognosis becomes worse. Lymphatic absorption helps in the spread of tuberculous mischief and is unfavorable. Extension by bronchial insufflation greatly increases the gravity of the prognosis. Arterial conduction produces scattered patches in the lungs, tubercle of the meninges, kidneys, and spleen, and its prognosis is most unfavorable. Tuberculosis of the larynx is always secondary to a lung lesion, no matter how ill marked or undetectable the lung lesion may be. Infection of the intestines is nearly always a precursor of the end. The second stage of pulmonary tuberculosis is never without pyrexia. The higher the fever the worse is the prognosis, but the worst feature is the hectic fever. Hemoptysis is a much graver symptom in the second than in the first stage, and may be dangerous. Its dangers are: (1) Loss of blood, (2) shock with cardiac failure, and (3) fright. If a cavity is present, then the more highly pitched its percussion note and the more resistance there is to the percussing finger, the more favorable is the prognosis, since these conditions indicate that the cavity has a thick fibrous wall. Echoing rales indicate a further progress of the disease, a combination of second and third stages, and are unfavorable. Dyspnea is greater in fibrosis than in cavitation, but carries with it a more favorable prognosis when present in the former condition. Hemoptysis is the great danger of the third stage of pulmonary tuberculosis, and is often fatal. [J.M.S.]

7.—Saylor reports a case of **scarlatina pemphigoides**. The patient was a married man, having a family of 5 young children, whose ages ranged from 12 to 3 years, all of whom were attacked by the disease in a mild form, and recovered with no complication. On the fourth day of the rash the eruption became vesicular and the vesicles rapidly coalesced and formed large bullas, which burst soon after and gave to the skin a badly scalded appearance. The author ascribed the bullous eruption to the fact that the patient did not go to bed during the attack, or even report himself ill. [J.M.S.]

9.—Cullin, while syringing the ear of an old woman 78 years of age, removed a small ball of tortoise-shell which had been lodged there for some 30 years. [W.S.N.]

10.—Edgar describes a case of **atresia of the os uteri** produced by agglutination of the margins of the os, which interfered with labor. By tearing away some of the adherent tissue, the os rapidly dilated, the membranes ruptured, and labor terminated in about 2 hours. [W.K.]

1.—Maguire, in continuing the discussion of **prognosis in phthisis**, calls attention to the value of **pyrexia, general weakness, digestive disturbances, and hemoptyses**. The higher the fever the graver the probable result. The only pathognomic type of temperature is that in which the morning temperature is higher than the evening temperature; this is exceedingly rare, fails to occur in many cases, and, at most, is only present for a short time. General weakness associated with feebleness of circulation is very serious; or if associated with insufficient nourishment as a result of gastric disturbances, it is also of serious import. Maguire ascribes the gastric disturbances to a reflex produced by the disturbance of the pulmonary fibers of the pneumogastric. Hemoptysis is usually looked upon as more important than it really is; it occurs very frequently in other conditions. Repeated small hemoptyses may be a favorable rather than unfavorable sign in regard to health. Multiple, copious hemoptyses are more serious, but a simple, large hemoptysis without fever and without signs of pulmonary lesions may not mean grave disease. Hemoptysis may be merely the result of high feeding adopted in the treatment of the tuberculous condition. The second stage, or progress, is characterized by the gradual softening of the pulmonary tissues. The most significant sign is the large, bubbling rale indicating some inflammatory products in a cavity. Maguire prefers the name "echoing rale," and it is really more descriptive of its nature. The lesions may extend either by contiguity, by inspiration along the bronchus, or by extension along some of the vessels in the lung. From the lungs they may extend in various directions chiefly to the larynx and the intestines. Primary laryngeal tuberculosis is probably exceedingly rare. In the intestinal tract the appendix is probably more frequently involved than the other portions, because the bacilli remain in contact with its mucous membrane a longer period. Hemoptysis is now a grave symptom, and may be so profuse as to produce shock. In the third stage the serious symptoms are: dyspnea, which is due usually to the loss of lung tissue; heart-failure, characterized by blueness and coldness of the extremities; and pneumothorax. The latter condition is chiefly serious because of the shock at the time of occurrence. Hemorrhage is almost invariably due to aneurysm in a cavity. These aneurysms are probably produced by aspiration of the arteries during attacks of coughing. [J.S.]

2.—Malins describes his method of **operative treatment for fibroid tumors of the uterus**, reports 6 cases successfully treated, and gives the following indications for operation: 1. Social position is to some extent a guide, since the wealthy can afford to be invalids, while the poor must have relief that they may be enabled to perform their daily labor. 2. Excessive and persistent hemorrhage. 3. Occasionally the pain and discomfort due to pressure symptoms. 4. Rapid growth of the tumor, particularly if there are signs of associated complications. [W.K.]

3.—MacLagan discusses **intestinal lesions**, describing the various typical stages and suggesting that the lesions are more severe near the ileum on account of the greater quantity of lymphatic tissues there present. He dismisses the **toxin theory**, claiming that the bacilli act directly, and the symptoms are due to secondary infection by various forms of cocci. When the process of sloughing sets in the symptoms are more severe. When this sloughing process causes diarrhea, hemorrhage, peritonitis, etc., life becomes seriously threatened. He discusses a few of the symptoms, mentions the fact that the diarrhea may not occur, that hemorrhage is not necessarily fatal, but that peritonitis almost invariably is. He argues that a toxin cannot be present because all the glands are not equally affected, as would be the case if it circulated in the blood. [It is generally held, and we think with some justice, that the changes in the lymphoid glands are due to the direct action of the bacilli, and that the general symptoms of the disease, fever, etc., are due to the action of the toxin. As a matter of fact, filtered cultures of the typhoid bacillus produce definite symptoms when injected into animals, and this could hardly be a result of anything but the products of their activity. J.S.]

4.—Coates describes a curious case of **acute dilation of the stomach** occurring in an infant about 3 weeks old. The stomach was enormously distended, the urine scanty, the skin dry and shriveled, and the child badly emaciated. About 3 hours after taking food she manifested hunger.

Finally, after various forms of diet had been unavailing, the stomach was washed out daily, on each occasion considerable air, thick mucus, and curdled milk being removed. The child was also fed upon human milk, and gradually recovered. Various drugs were introduced after washing, but Coates ascribes the general benefit to the latter procedure. [J.S.]

5.—Brunton and Tunncliffe have made some investigations upon the presence of **aldehyds in whisky**, particularly **furfural**. This can be recognized by diluting the same quantity of whisky with an equal volume of water, and adding a few drops of sodium carbonate solution, and then a few drops of anilin acetate solution. A rose-color develops on shaking. Injected into animals in doses of 0.10 to 0.05 gm. it caused paralysis of the voluntary muscles, then clonic and tonic convulsions, and rapid and irregular breathing. All symptoms were very transient, usually lasting about $\frac{1}{2}$ hour. Large doses caused death by paralysis of the respiratory muscles. The substance was apparently excreted through the kidneys. Animals were then infected with spirit containing furfural, and spirit free from it; the differences were apparently not great, but the postintoxication symptoms were more severe in the former group. [J.S.]

6.—Ewart calls attention to some of the symptoms of **typhoid fever**. Sagnant or putrid feces are particularly dangerous when they are liquid; slight astringent treatment therefore seems to be indicated. Inactivity of the liver as a result of pyrexia and prolonged rest, may be best relieved by mercury. Tympanites is dangerous on account of the tendency to perforate, therefore active peristalsis is to be avoided. When there is fulness and tension and extensive dullness over the right iliac fossa it may be relieved by placing the patient for a few minutes, on the left side. The best medicinal treatment is that suggested by Wedgewood; it consists in the administration of 20 min. of the liquor of the bichlorid of mercury, and 15 to 20 min. of the tincture of bichlorid of lime every $\frac{1}{2}$ hour throughout the attack. The constipation produced by this method is relieved by daily injections of glycerin. Cold baths are rendered unnecessary. [J.S.]

7.—Rumley-Dawson reports a case of **complete transverse septum of the vagina impeding delivery** in a primipara aged 21. The dilation of the urethra indicated **urethral coltus**. After the incision of the septum the child was soon delivered quite easily and naturally. [W.K.]

9.—Munde mentions a case of **typhoid fever** in a boy 12 years of age. He had a most copious eruption of rose-colored spots. It was impossible to count them, as they covered every part of the body. They reached their maximum extent on the fifteenth day. [J.S.]

10.—Alexander reports the following case: A man 33 years old developed **psoriasis**. He was taunted by his fellow-servants, became depressed and suspicious, and finally required commitment to an asylum. He was given 15 gr. of thyroid extract, 3 times a day, and a farinaceous diet. In 3 days his mental condition was better, and in the course of time he recovered from the psoriasis. [J.S.]

11.—Spaight reports a case of **purpura** occurring in a girl of 9 years, without any other symptoms. The following day there were hemorrhages from all the mucous membranes, but 4 days after the onset the hemorrhages ceased, the patches began to fade, and 5 days later the patient had recovered completely. [J.S.]

7. A Report upon 170 Cases of Appendicitis. ROBERT T. MORRIS.

1.—Shands in the treatment of supracondyloid fracture of the humerus, especially when it is oblique and there is a constant danger of slipping, cuts down upon it and brings the ends of the bone together with kangaroo tendon, or sometimes he allows the drill to remain in position and act as a pin, and at the end of 2 weeks removes it; the drill in this case is long enough to project through the dressings. By this method the bone can be brought into better position, and one can feel more comfortable about its retention. In these days of antiseptic surgery there should not be the least hesitation about making a simple fracture, a compound one, as the incision allows the escape of the effused blood, and the surrounding tissue regains its normal condition quicker than before. When this method becomes more general stiff elbows from deformity will be fewer. [W.S.N.]

3.—Forbes has devised a brace to be used in combination with a plaster jacket to correct and retain correction of kyphosis of Pott's disease of the spine. The main dependence for the ultimate success remains in the surgeon's careful, continued, and thorough employment of retention appliances which hold the spine in the straightest possible position for a sufficient length of time for consolidation of the diseased bony structures. The brace consists of 2 strips of steel about 1 inch wide, the thickness depending upon the length, size, and weight of the patient. These are carefully adjusted while the patient lies on his back and extend from the pelvis on each side of the spine to the shoulders where they curve outward toward the arms; at the bottom they are joined by a heavy piece of steel which extends outward to get a good hold of the plaster and act as a fulcrum; further up at different levels the 2 lateral strips are joined by smaller pieces of steel, and the one at the level of the posterior axillary fold is longer and extended outward to receive straps which extend from the lateral strips over the shoulders and under the arms to meet them. The advantages of this are, it gives greater and surer leverage than others, and it retains the correct position of the spine better. A head brace can easily be adjusted to it, the cast lasts longer and can be made lighter, at the same time it retains its efficiency until removed. [W.S.N.]

4.—E. Mayer reports a case of recrudescing angina due to *Bacillus pneumoniae* of Friedländer. This microbe, a saprophyte, occurs frequently in the mucous membrane of the bronchi, rarely invading the lung; also, it manifests itself locally in stomatitis, ozena, rhinoscleroma, acute suppurative rhinitis, and, by extension, in parotiditis, otitis, bronchopneumonia, purulent pleurisy, pericarditis, pyelonephritis, meningitis, and in pyemic and septicemic conditions generally. It was first noted in pharyngitis in 1895, but few reported cases are on record. Out of 1,600 cultures from diseased throats it was but 8 times discovered. This affection with minute bacteriologic notes and the clinical reports of 5 cases is the basis of a Thèse de Paris (1895) by Hebert, M. Nicolle in conjunction publishing results in the Annals of the Pasteur Institute (vol. xi, 1897). Further, 5 cases are noted by W. C. C. Pakes, and 2 by A. Billet. With the case under consideration this completes the known literature on the subject. This case was first considered as a chronic diphtheria, later chronic recurring membranous pharyngitis, yet, though the patient, aged 19 years, previously had had a genuine diphtheria, at no time in the present illness was *Bacillus diphtheriae* of Klebs-Löffler found. In common with the other cases of this form of angina, there is thus a history of previous acute disease (scarlatina in one, amygdalitis, acute articular rheumatism, simple angina, in others), but the bacteriologic examination gives nothing but streptococci, staphylococci, and on further tests at times other microbes, as *Micrococcus tetragenus*, and in all cases *Bacillus pneumoniae* of Friedländer. One connection of these former ones is relative, but careful investigation, as in the present case, by A. J. Lartigan, must be convincing as to the pathogenesis of this angina being due to the bacillus of Friedländer. [J.M.S.]

5.—Goldan condemns the reckless way in which intraspinal cocaine is used, and from the anesthetist's standpoint believes the range of its usefulness is limited to cases in which a general anesthetic is contraindicated. When

cocaine is injected into the spinal canal it acts with the same uncertainty as it does when administered otherwise, and there is great danger of injury to the cord by accident, as in a case of a nervous man to whom he was giving an injection, who without warning jumped up and bent the needle at a right angle, but fortunately no bad result followed. In regard to some of his failures, if the injection had not been prepared and given by himself he would have thought that they were due to improper application, but the same care was used in all cases. In regard to the amount of fluid to be injected into the spinal canal, it is best to inject more than the amount lost, as the tension is equalized quicker than if the amount is less. As a general anesthetic he does not regard it as good as ether or chloroform, and its general employment would be a step backward rather than forward. [W.S.N.]

6.—Wachenheim discusses the diagnosis of empyema in children, with reference to the clinical standpoint, since in infants when pyema is not traumatic in origin the recognition of the process is not easy. A history of steady loss of flesh and strength attended by irregular fever is usual, possibly preceded by some infectious disease. Chronicity is marked, but unresolved pneumonia must be differentiated. Neither side is preferred and bilateral empyema is not rare. The general appearance of the patient is suggestive; prostration and emaciation, though present in other intrathoracic affections, are valuable in completing the diagnosis. Local inspection shows relative retardation and diminution of the respiratory excursion on the affected side, and occasionally obliteration or even bulging of the intercostal spaces. The apex beat may be displaced. The pulse is disproportionately rapid and the respirations shallow, accelerated, and with effort, though not grasping as in bronchopneumonia. The use of the pleximeter is denied, the most gentle percussion being the most effective. The note of dullness over the affected side increases downward; above, there may be resonance or tympany. In empyema of the left side dullness over Traube's space is very characteristic. Auscultation is not as valuable as in adults. Friction sounds are rare, and rales over the dull areas are decidedly against exudation. Egophony is too frequently present in pneumonia and too little in empyema to be of use. If both pneumonia and empyema exist there is dullness laterally, but respiration is more bronchial on the side where dullness is less pronounced, and the rales, present elsewhere, are absent over the most resistant and least resonant area. When hepatic or other abscesses are in question the most skilful may be puzzled. Exploratory puncture is of most value and since no harm comes if used with proper care in any case. This method of diagnosis is recommended. It must be noted that the leukocytes gravitate to a depth undesirable for puncture, so that the removal of a clear serum does not militate against the existence of empyema. Sacculation is rare, as is also an excessively thickened pleura in infants. If an exudate is present, puncture of the lung is usually avoided by choosing the area of greatest dullness and feeblest respiratory murmur, and by using a not too long needle. In pneumonia, puncture of the lung unintended may, however, prove of advantage, the slight traumatism seeming to start resolution, and the author has never seen ill effects result from it. [T.H.E.]

7.—Morris, out of a series of 170 cases of appendicitis, removed the appendix in 120, through an incision 1½ inches in length; 59 of these were at the acute stage and 61 were interval cases. [W.S.N.]

Medical Record.

6. Local Anesthesia in the Radical Operation for Inguinal Hernia. LEO B. MEYER.

1.—Smith in amputating a leg in which the circulation is impaired, as often exists in cases of senile gangrene, finds that the knee offers the best place of operation, and by making lateral flaps instead of anteroposterior ones, the likelihood of dividing the arterial supply near its origin is thus avoided. [W.S.N.]

2.—Allen concludes his paper on the neuron doctrine as follows: It has long been known that an injury to a nerve cell or nerve fiber is followed by degeneration which is sharply limited in extent. The application of the Golgi method shows that each nerve-cell (and its processes) is developed from a primitive cell, the neuroblast; hence it forms an embryologic unit. Moreover, to all appearances the separation of these units, one from the other, always remains complete. The neuron conception appears logically to follow. So far, it appears no more proved that the Golgi and vital methylene-blue methods give deceptive results, than the methods of Apáthy and Bethe do. The latter have had nothing like so wide an application as the former, and more extended investigation seems to be needed before we throw a servant apparently so faithful overboard. There seems a good deal of difference in the conceptions of different authors as to just what the neuron means. It will be remembered that the idea of continuity between neuron and neuron has never been without supporters. Even if the views of Apáthy are confirmed, and we have to admit the continuity of the neuro fibrils, it does not seem to follow necessarily that we must abandon our idea of the neuron as a functional unit. Its embryologic unity is not affected. It may be necessary to modify our views, but our conception of the existence of the neuron, as a means of explaining certain facts, we are as yet hardly called upon to give up. [A.B.C.]

3.—Ehrenfest says that to produce painless labor seems to have been the predominant idea in the experiments so far made in the use of medullary narcosis in obstetrical cases. To accomplish this we must make use only of a method: 1. Which does not carry with it too great danger for either mother or child and an exact opinion with reference to this point can be arrived at only after the statistics of morbidity and mortality resulting from medullary narcosis are established. 2. Which does not produce conditions more disagreeable than the pain we are endeavoring to assuage; and all the reports tell us of disagreeable symptoms following these injections, sometimes lasting longer than after the usual chloroform or ether narcosis. Cases of immediate high elevation of temperature with deep collapse are on record; such a great risk, indeed, does a woman take in exchange for labor pain. 3. Which does not produce complications during parturition; that is, does not change a birth, which under ordinary circumstances would be normal, into instrumental delivery. This point is by far the most important, since, notwithstanding the best antisepsis and asepsis, subsequent puerperal or gynecologic diseases are invariably more frequent after delivery by operative procedures. The statistics at present accessible seem to show a very high percentage of forceps delivery under medullary narcosis, probably due to the deficiency of a normal automatic help of the abdominal muscles, and this condition alone would contraindicate the use of medullary narcosis as a means of making a normal labor painless. In considering the use of medullary narcosis for purposes of examination or required operative work, Ehrenfest adds to the considerations already mentioned only the statement of Marx that, "explorations, versions, extractions, placental removal, were readily done with not quite as much ease as under chloroform." Hence he concludes that it seems more than doubtful whether we are justified at the present time in recommending medullary narcosis as a substitute for chloroform in obstetrics. [W.K.]

4.—Cutler and Elliott report a case of perforation of a typhoid ulcer without fecal extravasation. The patient was in the third week of an attack of typhoid fever, and was seized by a sudden, severe attack of abdominal pain. The abdomen was moderately distended, rigid, and tympanitic. Nothing abnormal by palpation except tenderness. The leukocytes had increased from 8,000 on the day before to 17,000. The pulse was 110; temperature, 103.8°. Perforation was suspected, and a laparotomy was at once per-

formed. The abdominal cavity was filled with a turbid fluid containing fibrinous flakes. Peritonitis was evident. No perforation was found, but 4 feet above the cecum a grayish-white mass was found on the inflamed gut. The outline of an ulcer the size of a quarter of a dollar could be plainly made out. It was just ready to slough. The affected area was turned in, Lambert sutures applied, and the patient made a good recovery. [A.B.C.]

5.—Cohn, in the treatment of laryngeal tuberculosis, divides it into 3 stages: The first, where infiltration is localized and has not as yet broken down, curetage and cauterization is of value. When lactic acid is used it should be applied directly to the affected spot, until a brownish or blackish slough is produced, as the use of this acid in a spray is of little value. Several applications may be necessary, and cocaine should be used before each. In the second stage antiseptic treatment will make the patient more comfortable by reducing the inflammation set up by infection of other germs, but it has little effect upon the tuberculous process. In the third stage relief by the use of morphia and cocaine is all that can be done. The process of infection by invasion of the disease through the epithelium is open to doubt, as the disease usually begins in the submucous tissue and the epithelium covering it remains healthy until ulceration occurs. This condition often deceives the patient, as in the first stage the swelling causes an impairment of phonation, while in the stage of ulceration this swelling subsides and the patient finds that he is once more able to talk, and at the same time feels more comfortable, whereas the disease has caused decidedly more damage to the larynx. [W.S.N.]

6.—Meyer performed a radical operation for an inguinal hernia on a fellow physician, and employed, locally, a 6% solution of B-eucain to produce anesthesia. The operation for the first minute was painless, but afterwards a sensation as if someone was squeezing the testicle was felt. This caused considerable distress as well as a nausea produced when the omentum was handled. It left the patient in a generally nervous condition for some time afterwards, and from this case he believes it better to employ a general anesthetic. [W.S.N.]

4. The Surgery of the Gasserian Ganglion. WALLACE NEFF.
5. The Treatment of Bronchitis in Infants and Young Children. SAMUEL S. ADAMS.

1.—When Kelly opens the abdomen for investigation, he makes an incision about 8 cm. long, and if the operation is for appendicitis or some pelvic disturbance, if the patient's condition permits he explores the region of the gallbladder and if a stone is found, performs a rapid and simple operation as follows: The hand is placed in the incision and runs along the abdominal wall until successively the crease in the liver that leads to the gallbladder and the gallbladder itself is found, when it is gently pressed between the finger and thumb until all the bile is squeezed out; if a stone is felt it is pressed against the abdominal wall, while with the free hand he cuts down to the peritoneum, making an incision about 4 or 5 cm. in length. A small nick is made in the peritoneum, the edges are then caught with mosquito forceps and the opening is enlarged. The gallbladder is then pressed into the incision, opened, and the stone removed. If the gallbladder is healthy he hesitates to drop it; after closing it with buried quilted sutures, he closes up the wound without drainage. On account of the distressing conditions caused by these foreign bodies he believes it better to remove them as long as the abdomen has been already opened and there is very little additional risk. [W.S.N.]

2.—Stengel says it is likely that in rheumatism, as in

pneumonia, a variety of microorganisms of moderate virulence may operate to produce a similar pathologic result. The result is a serous or serofibrinous inflammation of the joints, the pleura, the pericardium, endocardium, etc., with as a rule a moderate systemic infection or intoxication. In regard to the **treatment of rheumatism** we should remember that many cases tend to spontaneous recovery; that complications are frequent and more likely to occur in protracted cases; that probably as a rule the complications are secondary to the joint disease and not to the primary lesion that was the infective focus. Aside from the use of sodium salicylate, the author speaks highly of the local application of a 10% or 20% ointment of salicylate of methyl covered with lint or oiled silk. It both relieves pain and combats the disease. In gonorrheal rheumatism he secures rest with a plaster-cast. In 3 cases of obstinate rheumatism he used antistreptococcus serum with encouraging results. [A.B.C.]

3.—Gordinier reports 2 cases of **sporadic trichinosis**. He speaks of the former difficulty in diagnosing these cases, and thinks many cases have been overlooked and incorrectly diagnosed. Reference is made to the discovery by Brown, of Johns Hopkins Hospital, that in trichinosis there is an enormous increase in the eosinophiles in the blood. This now enables us in most cases to make a proper diagnosis. In the author's first case the eosinophiles composed 77% of leukocytes, and there was a remarkable reduction in the polymorphonuclears. In the second case the eosinophiles composed 31.9%, and the polymorphonuclears 49% of the leukocytes. In all, there have been 20 cases of trichinosis reported since Brown's original paper on the subject, and in 19 of these the presumptive diagnosis was made from a pronounced eosinophilia, which was subsequently confirmed. [A.B.C.]

4.—Neff, in the prognosis of **excision of the Gasserian ganglion for trigeminal neuralgia**, states the immediate result is either relief or death; the latter may be caused by hemorrhage (uncontrollable), shock or sepsis; while the unpleasant remote results are recurrence, due to an incomplete operation, destruction of the eye, paralysis of the muscles of mastication, or an abscess of the brain may develop later, but usually the patient is willing to take these risks for the sake of relief from the intense pain. In these cases medical treatment affords but little ease, while electricity sometimes palliates; this leaves some surgical procedure the only course open. The simplest form of operation is a neurotomy, then neurectomy, and neurexeresis, but these only give temporary results, and when the nerve has been repaired, the pain returns; the same may be said of dividing the nerve near its central origin, therefore most of these operations have been abandoned in favor of extirpation of the Gasserian ganglion, and of the numerous methods he prefers the temporal route, and his conclusions are as follows: 1. Trigeminal neuralgia is an ascending neuritis, peripheral in origin. The second and third branches, rather than the first, are the ones most likely to be involved. 2. If the disease persists after several months' trial with drugs, electricity, etc., surgical intervention is indicated. 3. If only one branch is involved and the disease is not of long standing, as much as possible of the affected branch should be removed with a view of relieving pain and preventing the upward progress of the disease. 4. If more than one branch is involved, and the pain is severe, and has persisted for a long time, the ganglion should be extirpated, all other means having failed. 5. The temporal route should be followed, the Hartley-Krause, or preferably, Cushing's modification of it, being the most rational procedure. 6. Pain will not recur with original severity in more than 1 or 2% of the cases operated upon, or in any degree in more than 4 or 5%, and is invariably due to an incomplete operation. 7. It is important to remove the ganglion and its branches intact in order to be certain of the completeness of the operation, and to insure a careful and thorough microscopic examination of the specimen. 8. The present mortality is about 10%. Increased experience and an improved technic will undoubtedly diminish this mortality, and dissipate the risks of this hitherto most formidable, difficult, and dangerous operation. [W.S.N.]

5.—Adams discusses the **treatment of bronchitis in children**. The most important prophylactic treatment is a daily bath with water at a temperature of 80° to 90° F., fol-

lowed by gentle rubbing. The child should not be confined too rigidly to the house. A dry and cold atmosphere is wholesome. The sleeping-room should not be warmer than 65° F. The direct treatment of the disease involves local applications, such as a cotton jacket, inhalations of various substances, such as a compound tincture of benzoin, creasote, etc.; the administration of expectorants, such as ammonium iodid, although this should be used with great caution; and general rest. Opium should not be given unless the cough disturbs sleep. Emetics should be given only when there are some gastric symptoms, and stimulants of various kinds only when indicated. Blisters should never be used. In cases of passive pulmonary congestion, either flagellation or a hot bath may relieve the symptoms. [J.S.]

3. A Plea for Larger Doses of Antitoxin in the Treatment of Diphtheria. JOHN H. MCCOLLOM.

3.—In 1881 the mortality from **diphtheria** in Boston was 35.7%. In 1899 it was 9.76%. This diminution in mortality is principally due to the use of **antitoxin** and to the treatment of the patients in hospitals. There has been a marked reduction in the death-rate following tracheotomy and intubation since the introduction of antitoxin. No hard and fast rule can be made regarding the use of the serum; the agent must be given until the characteristic effect is produced on the diphtheric membrane; in some cases 4,000 units will accomplish this, in other instances 60,000 or 70,000 units may be required. In operative cases the beneficial effect of large doses of antitoxin has been marked, preventing, in many cases, the extension of the membrane to the smaller ramifications of the bronchi. No case of diphtheria in the acute stage should be considered hopeless. Antitoxin should be administered in each and every instance. In many cases the large doses of antitoxin mentioned above are essential, but if the patient is seen early enough smaller doses of 4,000 to 6,000 units suffice. Notes of 11 cases form a part of the paper. [J.M.S.]

9.—Webster finds that the separation of the recti-abdominis and stretching of the linea alba is more common in hard-working women, and especially those who work hard during the last half of pregnancy and too soon

after labor, while it is often found in those subjected to tight lacing, and a larger proportion of women suffer from this trouble than is usually supposed. The examination of a large number of primigravidae demonstrated that the majority had some separation of the muscles. The symptoms produced by the displacement of the viscera varies, no set being typical, but in all his 51 cases in which he **stitched the muscles together**, the general condition was improved; in several where coexisting displacement of the kidney and uterus was found, it too was corrected. In those refusing operation, loose garments, with a silk-elastic abdominal binder gives some relief, but at the same time causes more or less discomfort, and weakens the muscles still more. [W.S.N.]

6. The New York Academy of Medicine. Artificial Infant Feeding. A. JACOBI.

1.—Forchheimer contributes an article on **cough, simulating whooping-cough, in influenza**. The peculiarities of the cough were that it always moved in epidemics; it was decidedly contagious; it usually developed at night; it was like that of whooping-cough except that the peculiar whoop was not so characteristic; it was accompanied by the ordinary congestive symptoms of whooping-cough; and it was followed by vomiting and expectoration. On the other hand, the peculiar blue color of the mucous membrane and of the tongue was absent. The ulcer of the frenulum was present and if anything better marked than in whooping-cough. The involvement of the bronchial tree varied with the individual and with the epidemic. If the original attack of influenza was of the respiratory form, the chances of the development of a bronchitis or a pneumonia were greater than in those cases in which the original attack was confined to the gastrointestinal tract. If left to itself the disease lasted as long as 6 or 8 weeks, but in the majority of instances the symptoms can be aborted in about a week or 10 days. It seems to the author that in order to produce the symptoms of whooping-cough there must be a certain anatomic location of the cause, and this cause need not of necessity be the specific cause of whooping-cough; but any irritant localizing itself in or upon a certain part of the respiratory apparatus. Full doses of quinin materially reduced the duration of the disease. It was given by Forchheimer in the following doses: 1 decigram less than the age in years and 1 centigram less than the age in months. When the cough had developed thoroughly, phenacetin or antipyrin gave great relief. In very bad cases codein was required in full doses and sometimes it became necessary to give chloral at night in order to insure sleep. Belladonna was a disappointment as a rule, but in some cases its effects were very gratifying. [J.M.S.]

2.—See PHILADELPHIA MEDICAL JOURNAL, Vol. V, p. 1000.

3.—Acker reports the case of a boy, aged 11 years, who had been unconscious for 3 days. The child was in a comatose condition, with tonic spasms when first seen. Lumbar puncture was done at 4.30 P.M., and though no fluid came away, in an hour the patient began to speak and take nourishment and at the same time the muscular spasms relaxed. Examination of the blood showed a large number of estivo-autumnal organisms. He also reported the case of a girl, aged 8 years, who was taken ill 3 weeks before she was first seen with coughing spells and high fever at night. This was followed by swelling of the lower eyelids and of the extremities, accompanied by great shortness of breath. The patient had two severe convulsions just before being admitted to the hospital. The urine contained a few epithelial, granular, and hyalin casts with a few blood-corpuscles and many leu-

kocytes. While in the hospital the patient had severe clonic convulsions that lasted about 10 minutes. The blood contained numerous estivo-autumnal organisms. The patient was cured after an attack of typhoid fever. On account of the nephritis that complicated this case, there is some doubt whether the convulsions and coma were directly produced by the malarial organism. It is reasonable to take the view that both the kidney disease and coma were caused by the malarial parasite. [J.M.S.]

4.—Park has analyzed 93 cases of diphtheria that were treated in the Willard Parker Hospital in 2 months. Of these 14 died, or 15%. Forty-two of the patients received 1,000 antitoxin units; and 7 of these died, or 16.6%. In this group there were 7 intubations, of which 4 recovered, and 2 laryngeal cases that did not require intubation, both of which recovered. Fifteen patients received 2,000 antitoxin units, and 7 died, or 13.7%. Of this group there were 6 intubations, 4 of which recovered, and 4 laryngeal cases not requiring intubation, all of which recovered. In the **treatment of diphtheria the dose of antitoxin** may be formulated as follows: In very mild cases, 1,000 to 1,500 units for the first dose. In moderately severe cases, 2,000 to 3,000 units for the first dose. In very severe cases 4,000 to 5,000 units for the first dose. In laryngeal cases, 2,000 to 5,000 units, according to their severity. For children under 1 year the author recommends about $\frac{1}{2}$ less than for older children and adults. He believes that the amount of swelling of the throat and the extent and nature of the membrane are better guides to antitoxin dosage than the general condition of the patient. If at the end of 12 hours after the injection the inflammation is advancing, or if at the end of 18 hours the inflammation has not clearly begun to subside, as shown by lessened congestion and swelling, a second dose of antitoxin should be injected. In a few cases a third dose is required at the end of 24 to 36 hours. For the bronchopneumonia and sepsis complicating some of the worst cases of diphtheria, antitoxin is generally of no avail. It is better to give too much antitoxin than too little, although moderate doses seem to accomplish as good results as very large ones. [J.M.S.]

5.—After a study of the **chemic compositions of antitoxic serums** Park is of the opinion that antitoxins are, in all probability, substances having the properties of globulin. They cannot with our present knowledge be separated from that portion of the blood-serum which, in susceptible persons, produces disagreeable effects. The fact, however, that the antitoxic serum from some horses is scarcely at all deleterious, leads us not to give up the **attempt of procuring a serum** either by selection of animals or by the treatment of the serum itself which, while antitoxic, is not to any important degree deleterious. [J.M.S.]

6.—Jacobi reports the case of a baby who was suffering from rachitis. The spleen was so much enlarged that it filled $\frac{1}{2}$ the abdominal cavity. The child had been breast-fed. [J.M.S.]

6. A Case of Multiple Neuritis with Atrophy; Fibrillary Twitchings, Cramps, and Exaggerated Reflexes; Two Years' Duration and Recovery. WILLIAM JAMES MORTON.

1.—Dercum has made some careful studies upon the **ability to recognize objects by handling them**. In 41 cases of hemiplegia astereognosis was complete in 13 and partial in 7. In three of the 13 cases tactile sense was lost; in 10 it was present; completely in 6, and partially in 4.

Pain, temperature, and pressure sense were sometimes preserved and sometimes lost; the spacing sense was lost in 10 cases, diminished in 1, and present in only 1. In 4 of the cases in which it was lost all the other forms of sensation were preserved. In the 1 case in which the spacing sense was preserved, the localizing sense was deficient. The muscular sense, that is, the ability to describe correctly the position of the fingers, was present in only 1 of 9 cases in which it was tested. Stereognosis was present in a case in which there were pronounced secondary contractions, and in another in which there were ceaseless athetoid movements. Dercum studied various other morbid conditions with the following results: In 5 cases of diplegia, 2 exhibited stereognosis on both sides, and 3 on one sides. In 16 cases of locomotor ataxia total **astereognosis** was present in both hands in 3, and partial astereognosis in 2 cases. In 3 of these there was loss of muscular sense, and in none loss of localizing sense. In 3 cases of ataxic paraplegia astereognosis was present in 2; spacing sense was lost in both and muscular sense diminished or lost, and localization preserved. In 2 cases of multiple neuritis astereognosis was present in both hands of one. Various other conditions were also studied, such as myelitis, multiple sclerosis, syringomyelia, etc., but all were normal in this respect. Dercum concludes that the most important factor in determining astereognosis is the loss of the spacing sense, whilst preservation of the other senses is insufficient to enable the subject to recognize objects. [The author is in error in stating that he first used the words "stereognosis" and "astereognosis"; both have been employed in current medical literature for several years by authors whose articles he quotes. J.S.]

2.—Thomas reports the case of a young woman who gradually became paraplegic. At the end of 10 months there was sensory and motor paralysis and loss of control over the sphincters. Up to this time she had suffered considerably, but after this there was no pain. For 13 years she remained in this condition, contractures and bedsores appearing in the lower half of the body and then death occurred. There was an **endothelioma of the dura** of the cord just below the cervical enlargement; this contained true bone, and presented, in many respects, the characteristics of **psammoma**. It is probable that an early operation would have cured the patient. The second patient developed at the age of 6 years, after a slight injury, some weakness in the right upper extremity. This was followed by spasm and later, by complete paralysis of the arm and paresis of the leg. The tendon reflexes were increased. Fifteen days later the child died suddenly as a result of hemorrhage into a glioma that had invaded the cervical enlargement. The case is interesting particularly in reference to the etiology of the tumor. The symptoms first developed immediately after the injury. Thomas, however, believes that this was due not so much to the growth of the tumor at this time, as to the production of a slight hemorrhage into its substance. [J.S.]

3.—Meyer suggests the **reconstruction of serial sections of the brain** by drawing them on glass plates which are then superimposed. The method is rapid and satisfactory and makes it possible to take apart the plates for future study. [J.S.]

4.—Bullard has had a series of experiments performed upon cats in order to determine the **effect of intracerebral pressure**. The brain of a cat under ether will bulge through a trephine opening, and requires from 8 cc. to 17 cc. of water to maintain it in its normal position. Any external factor increasing blood-pressure will cause greater bulging of the brain. Heavy blows upon the skull also increase the cerebral pressure, the maximum observed being 47 cm. This rise is apparently independent of the general arterial pressure. [J.S.]

5.—Kellogg describes a form of **subacute pressure neuritis** caused by slight trauma to the nerve. The symptoms are, tingling, or numbness in the little and ring fingers, followed by paresthesia in the ulnar distribution, and finally, well-marked anesthesia with vasomotor contraction in the fingers. There may be some disturbance of motion. The cases last for weeks, or even months, but complete recovery usually ensues. Treatment consists of removal of the cause, hot-air, massage, electricity, exercise, etc. [J.S.]

6.—Morton reports a remarkable case in which apparently contradictory symptoms were present. The patient, a man, at the age of 32, contracted a **severe fever** in Africa,

characterized by chills affecting the left half of the body. About two weeks after the onset there were pains in the left shoulder passing into the arm, and accompanied by swelling of the fingers and shiny skin. Later the calves of the legs became readily fatigued, there was weakness in both arms, and atrophy in the muscles of the left. The nerve-trunks of the left arm were very sensitive; the reflexes were greatly exaggerated. This exaggeration was variable from time to time. Later he developed severe cramps, and then atrophy of the muscles of the left shoulder, accompanied by fibrillary twitchings. There was typical reaction of degeneration in these muscles, but ultimately complete recovery occurred. Treatment was **antimalarial** and the application of static electricity in various forms to the affected muscles. [J.S.]

1.—Clayton has studied **general paralysis as it occurs in the Royal Navy**. He concludes that: 1. There is no one factor, invariably antecedent and connected directly with the disease. 2. That the influences that act remotely are usually conditions tending to interference with nutrition, and to promoting the growth of less highly organized tissues, while the proximate influences probably act by lowering vitality. 3. That the infrequency of nervous heredity argues against the disease being a mere wearing out of the highest nerve-tissue, as these persons, the nutrition of whose nervous system is so readily disturbed, would otherwise be the chief sufferers. 4. That a "specific" cause as yet unknown, capable of developing the disease *per se*, though often aided by various factors, and which usually selects those apparently most healthy and vigorous, both in mind and body, seems to be indicated by all the evidence. Assuming the morbid condition to be a parenchymatous degeneration there seems justification for considering the possibility, either of the elaboration within the body of some material, toxic to the highest tissues, or the failure to form something necessary for their nutrition. Though the nervous system is chiefly affected, a general malnutrition is evident. It was found that the use of alcohol, as a remedy, increased the number of seizures, and it was also noted that the seizures were more frequent when there was a change to a southerly wind. The indications for the treatment of the seizures are: (1) To assist in the destruction and the elimination of toxins by improving the condition of the blood, as by oxygen and by acting, as in uremia, upon the various excretory organs; (2) to relieve cerebral congestion by the use of the ice cap and ergot; (3) to check the explosiveness of the neuron by the administration of chloral in 15 to 20 grain doses. An equal amount of ammonium bromid perhaps prolongs the action of the former drug; (4) to maintain the strength of the patient and to avoid complications, such as hypostasis, inhalation of food and its results, diarrhea, and bedsores. In a suspected case a system of life in a warm climate with almost vegetarian diet seems worthy of trial. These requirements should be combined with absolute rest, attention to the excretory organs, and abstinence from alcohol. In the management of the established disease, the prevention of bedsores is of great importance. In order to accomplish this object, confinement to bed when the patient becomes liable to fall about or is constantly wet and dirty is essential. [J.M.]

4.—Gibson reports a case of **diplococcic infection**, resulting in **pleuropneumonia**, accompanied by great constitutional disturbance. In spite of treatment the patient steadily became worse and died. At the necropsy it was found that the aortic segments were ulcerated and extensively destroyed. On microscopic examination, the thrombus ad-

herent to the ulcerated aortic valves, was found to consist of diplococci with leukocytes and fibrin. It is highly probable that all cases of acute and subacute endocarditis are of microbic origin, and all may be therefore termed infective. The recognition of cases of the disease is undeniably difficult, because we find that not infrequently there is a total absence of any characteristic physical signs. [J.M.S.]

5.—MacLennan reports a case of postoperative pulmonary embolisms, simulating pneumonia after an operation upon a carcinoma of the breast. Usually emboli cause sudden death, and are due to sepsis, but in this case the patient lived 6 days, and the wound was found in normal condition at the necropsy. No embolus was found, but some of the branches of the axillary vein showed signs of thrombi. [W.S.N.]

1. Injurious Suggestions in Cases of Injury. W. SEIFFER.
2. Polyneuritis After Malaria and Landry's Paralysis. R. BAUMSTARK.
3. Experimental Investigations in Catheter Sterilization. M. KATZENSTEIN.

1.—Seiffer cites a number of instances showing the baneful effects of inconsiderate suggestion. The patients who had received trifling injuries were examined by physicians, and the latter, in stating the diagnosis, gave a gloomy prognosis. As a result some of the patients developed hysteria, others traumatic neurasthenia. [These things are not so likely to occur in this country: First, because our medical terms are not to any large extent taken from the vernacular and are hence unintelligible to the patient; and second, physicians are more cautious or more reluctant in giving a hopeless prognosis directly to the patient. D.R.]

2.—A case of multiple neuritis due to malaria in a German who for a comparatively short time resided in the tropics (Kamerun). [D.R.]

3.—Katzenstein reports a series of experiments which he undertook to determine the best method of sterilizing catheters. He found that by washing in soap and sterile water and allowing catheters to remain in 1:1000 mercuric chlorid the results by bacteriologic investigation were not satisfactory. The disinfection with formol vapor according to the usual methods is also unsatisfactory. He describes an apparatus which he devised for the sterilization of catheters by means of which it can be accomplished satisfactorily in 10 minutes. The formol vapor is developed from trioxymethylen, heated to a sufficiently high temperature to cause the vapor to stream through the catheters. Because of its affinity for formol, dehydrated phenylhydrazin is used at the other end to help draw the vapor through. [M.B.T.]

1. A Case of Diffuse Chronic Skin Edema. HEINRICH ROSIN.
2. A Reduplication of the Left Index Finger and a Triple Right Thumb. JOACHIMSTHAL.
3. The Amount of Eye Disturbance in Hemianopsia.
4. Polyneuritis after Malaria and Landry's Paralysis. R. BAUMSTARK.
5. Another Case of Polyneuritis Following Malaria. C. A. EWALD.

1.—Rosin's patient was a woman, 42 years of age, in whom an edematous swelling developed, beginning in the face and extending down on to the chest, over the back of the hands, the neck, the shoulders, the forearms, and the back, and later also to the legs. Excepting a functional murmur over the heart, all other signs of disease were absent. There was no albumin in the urine and no casts. The condition did not resemble myxedema and there was a normal thyroid. The edema being chronic, it could not be placed in the category of ordinary angioneurotic edema, and the author felt he could do nothing more than call it a diffuse chronic edema of the skin, probably dependent upon some circulatory disturbance of unknown nature. [D.R.]

2.—The case of a girl 9 years old is reported who had a double index finger of the left hand and 3 thumbs of

the right hand. The parents and a younger brother were normally developed. The anomaly is carefully described and photographs and x-ray pictures are given. [M.B.T.]

5.—The patient was a man 31 years old, who had lived in the Camarons and had had a mild attack of malaria during which, however, the parasites were not found in the blood. Thereafter he developed girdle sensation, weakness in the legs, impairment of memory, loss of appetite, and nausea. During the sea voyage the symptoms became aggravated, and there were involuntary discharges of urine. After his arrival at Berlin it was discovered that he had paralysis of the lower extremities, loss of patellar and skin reflexes, and tenderness of the calves to pressure. Speech was hasty and the patient often lost the thread of conversation. Later Romberg's symptom developed. The pupils reacted sluggishly in accommodation, but properly to light. The man improved gradually, and nothing remained except the paralysis of the extensors of both great toes. Ewald believes that the case was one of multiple neuritis due to malaria. He also relates another interesting case in which the diagnosis was difficult. A man who, with the exception of a short journey to Wiesbaden, had never left Berlin, and had lived in a healthy part of the capital, developed a tertian intermittent fever lasting 8 months, and resisting all forms of treatment. The blood examination gave negative results. There was a suspicion of syphilis, but the patient did not improve under antisyphilitic treatment. Ewald was unable to come to a conclusion, except that the man may have been a malingerer, since he had become a pensioner and was not inclined to resume work. One day, shortly before his expected dismissal from the hospital, the temperature suddenly became normal and remained so. Of course, as Ewald admits, it is difficult to conceive how a man could simulate a tertian intermittent fever during such a long period of observation. [D.R.]

5. The Physiology and Pathology of Bile-Secretion. ALBU.

1.—Will be abstracted when finished. [See PHILADELPHIA MEDICAL JOURNAL, July 29, 1900.]

2.—Oppenheim last year described a case of facial palsy developed in childhood in which a current applied to the facial nerve in the healthy side too weak to produce a noteworthy contraction on that side, brought about a contraction of the muscles of the chin and lower jaw on the paralyzed side. He explained this on the basis of a passage of fibers from the healthy facial nerve across the median line into the adjacent muscles. Bernhardt took issue with him, and attributed the phenomena to an interlacing of the muscles. Mohr, in the present paper, proves that Oppenheim's view is the correct one. [D.R.]

3.—In his treatment of obesity, Kisch allows the patient 160 grams albumin, 80 grams carbohydrate, and 11 grams fat per day. As to fluids, the plethoric obese may drink according to desire. In the anemic obese, the quantity is restricted. In order to regulate walking exercise, the patients are advised to employ a pedometer which, when placed in the pocket, registers the number of steps taken. Daily weighing is important, but, to be of value, it must be associated with various bodily measurements. The dynamometer is employed to control the strength—if there is a loss of strength, the treatment is too intensive; the sphygmograph should also be called into use, as it affords a check on the heart-action. It is likewise important, especially in fat anemics, to determine the difference between the water ingested and that eliminated in the urine. The quantity of water allowed should be just that which is quickly eliminated from the body. The patient in whom the occurrence of debility is to be feared during the course of treatment, careful metabolic studies are necessary. They are, however, difficult. [D.R.]

4.—Miura recommends a suction cup, provided with attachment for a rubber tube in the treatment of anasarca. The apparatus is filled with saline solution and in-

verted over a tense area that has been sterilized and incised in several places. In the course of a few hours 1 or more liters of fluid can thus be drawn off. [D.R.]

6. The Question of Traumatic Spinal Diseases. M. OBERST.
7. The Diagnosis of Death from Starvation.

1.—Leutert has written an elaborate article on **suppuration of the middle ear**, and in it he discusses thoroughly the formation of cholesteatoma. Speaking first as regards the diagnosis of the original focus of pus formation in the ear, he says that the diagnosis is greatly helped by noticing the position of the perforation in the drum. It is, however, possible to have a perforation in the attic without extension into the lower part of the tympanic cavity, and in these cases the drum membrane is not perforated; indeed, sometimes is even of a normal color. If the perforation is seated in the lower portion of the drum, especially in the anterior part, it is most likely that the pus comes from the eustachian tube. A large perforation near the middle of the drum indicates the involvement of the tympanic cavity alone. When the attic is involved the perforation is found in Shrapnell's membrane and does not extend to the bony margin. If the perforation does extend to the margin and is located in the posterior portion, it is an indication that the antrum is the seat of the disease. Involvement of the attic alone is a very rare condition. As to the formation of cholesteatoma, it is a noteworthy fact, that in order for the pavement epithelium to proliferate and form the horny mass, there must be destruction of the already existing cuboidal epithelium. The growth of the cholesteatoma is favored by what might be termed a middle grade of inflammation, and when the degree of inflammation extends above this, the chances for the proliferation of the epithelium is unfavorable, even to a cessation of its growth. If the degree of inflammation is too slight, the growth is slow and the resulting mass only becomes of importance after adult life has been reached. Koerner says that one should distinguish between the formation of true cholesteatoma and the formation of a mass of proliferated epithelium. He says that true cholesteatoma is a fairly frequent disorder and exists only where there is no perforation of the drum. He goes on to recite a number of instances in which this may be noted. [G.B.W.]

2.—After a brief review of the literature on **ankylosis of the spinal column**, including rhizomelic spondylosis, Kühn reports his own case—a girl of 12, of rheumatic ancestry, who began to have pains in the ankle at the age of 8; the right knee also became painful and enlarged, and later the hands were involved. The spine became distorted and the head deflected toward the right, and eventually the hip-joints were involved. The knees assumed the genu valgum position, the movements of the spine were much limited, and the patient could lift herself from the bed only to a slight degree. She could not stoop to pick up anything from the floor. The shoulder joints were free, but the elbows could not be fully extended. The author looks upon the case as one of **arthritis deformans**; it was somewhat atypical, in that the small joints were still movable, although they were decidedly swollen. In typical **rhizomelic spondylosis** the small joints escape. The x-ray pictures gave a good view of the deflection of the spinal column. [D.R.]

3.—There has been a marked increase in the **frequency of cancer in Hamburg**, affecting both sexes, but especially the male. Thus, in 1873 there were 65 deaths from carcinoma for each 100,000 of living inhabitants; in 1899

there were 100; 8 for each 100,000 living. Roger Williams, who had also noticed an increase in the mortality from cancer, believed that it was attributable to an improper mode of living, and he accused particularly excessive meat diet with insufficient bodily exercise. A statistical study of the different strata of the population of Hamburg and their liability to cancer shows that the mortality from the disease is independent of the water-supply, the density of population, wealth and poverty, altitude, or sub-soil. A very striking result shown by Reiche's study is the enormous preponderance of carcinoma of the digestive tract. There has been a particular increase in carcinoma of the esophagus, to which the male sex is far more liable than the female. The author does not offer any explanation of the spread of cancerous disease, simply giving the facts without comment. [D.R.]

4.—**Roborat** is a white, almost tasteless, impalpable powder, prepared from grain; it is easily borne and nearly completely utilized in the system. Uric acid, creatinin, and phosphates are diminished in the urine under its use, and it is capable of increasing the body weight. It also contains an abundance of lecithin and glycerin phosphoric acid, and the author recommends it as a valuable nutritive substance. [D.R.]

5.—The symptoms of **sausage poisoning (botulismus or allantiasis)**, which must be separated from those of meat poisoning, are usually severe and of long duration. They set in from 12 to 24 hours after the ingestion of the sausage, and consist of malaise, and feeling of pressure in the stomach, and nausea, and sometimes vomiting; diarrhea may be present, and also dyspnea and a sense of suffocation. The prostration is generally well marked and, as a rather characteristic phenomenon, there is a diminution of all secretions and a consequent dryness of the skin and mucous membranes. Frequently there is an inflammatory process, with membranous deposits in the throat resembling diphtheria. Nervous disturbances, particularly of the eyes, are common; foggy or color vision, transitory blindness, and sometimes diplopia, are noticed. The pupils are usually dilated, and react to light sluggishly or not at all. Ptosis is a frequent, and by some considered a pathognomonic symptom. There is dysphagia and sometime severe cough on swallowing, and eventually an inspiration pneumonia. The voice is hoarse and toneless. Fever is usually absent, unless there are complications. The pulse is small and feeble. Strangury and ischuria may be present. Death occurs in from 8 to 10 days in consequence of respiratory paralysis. Examination at autopsy reveals no pathognomonic features. The author reports 8 cases of this affection produced by eating improperly smoked pork sausage. No examination of the sausage was made, as none could be obtained. Of these 8 persons, 1 died. [D.R.]

6.—It is undoubtedly true, that in many cases a rarefying **osteitis of the spine** will develop several weeks or months after an important injury, and finally the disease may progress until considerable destruction of tissue has taken place. Some authors have applied the name "Spondylitis traumatica" to this condition, but this is a misnomer, as the lesion is not of an inflammatory nature. Rather it resembles such cases as fracture of the neck of the femur, in which, owing to early use of the part, a bending of the neck occurs, causing a condition very closely allied to coxa vara. [G.B.W.]

7.—The author takes issue with Hartmann (PHILADELPHIA MEDICAL JOURNAL, October 20, 1900, p. 747) in his statement that there are no characteristic signs of death from **starvation**. He believes that an examination of the urine may sometimes be possible, and in that case the presence of **acetone** or **diacetic acid** shown with the ferric chlorid test would be diagnostic. [D.R.]

1. The Neutral-Red Staining of Leukocytes. HUGO MARCUS.
2. Acetopyrin a new Antipyretic. JOSEF WINTERBERG and ROBERT BRAUN.
3. A Case of Elevation of the Uterus with Separation of its Body from the Vaginal Position. H. LUDWIG.
4. Hyperglobulia and Enlarged Spleen. Hyperglobulia and Splenectomy. V. COMINOTTI.

1.—Marcus has carried out experiments similar to those reported by Plato (PHILADELPHIA MEDICAL JOURNAL, November 24, 1900) and has found that **normal leukocytes are stained in the fresh state by a neutral-red**, while those that are damaged do not stain. [D.R.]

2.—**Acetopyrin** is a compound of acetyl-salicylic acid and antipyrin. It is a crystalline powder, soluble with difficulty in cold water, but more readily soluble in warm water, and easily soluble in alcohol, chloroform, and warm toluol, and with difficulty in ether and petroleum ether. The authors have experimented with it in about 100 cases and have found that it has advantages which render it superior in rheumatism to sodium salicylate and other derivatives of salicylic acid. It does not depress the heart. [D.R.]

3.—Of all the changes in the position of the **uterus**, its **elevation** is the most rare. It may be caused by adhesions to adjacent organs above, drawing the uterus upward, as has been observed after cesarean section; or it may result from a tumor developing in the small pelvis, pushing the uterus upward; or a tumor above, as of the ovary, by its upward tension, may lead to elevation of the uterus. The changes in position of the uterus often lead to changes in the form of the organ itself, increasing its length and sometimes so distending the cervix as to entirely obliterate the cervical canals, and even to sunder it from the body of the organ. The writer has never seen a case of this kind, but Iversen reports one occurring in a patient aged 3½ years. The writer reports the case of a patient aged 15 in which the upward tension, produced by an ovarian tumor, had raised the uterus until the cervix appeared as an elongated fibrous cord, scarcely recognizable. [W.K.]

4.—After briefly discussing the conditions under which **hyperglobulia** (an excessive number of red corpuscles) occurs, Cominotti reports the case of a woman, 33 years old, in whom, on account of an enormous enlargement of the spleen of obscure causation, a **splenectomy** was performed. The spleen weighed 4½ kilograms (about 9 pounds). Several blood examinations before the operation showed from 7,000,000 to 7,500,000 red corpuscles, 6,000 to 6,300 white cells, and 75 to 80% hemoglobin. Five days after the splenectomy the red corpuscles were 6,500,000, the white 7,200, and hemoglobin 70%. Two days before the patient's death of sepsis, about a month and a half after the operation, there were 5,300,000 red cells. No microscopic examination of the organs was made. The occurrence of hyperglobulia in cases of disease of the spleen or after splenectomy has been attributed to the failure of the blood-destroying action of the spleen; but as in some cases of splenectomy there is hypoglobulia, a satisfactory explanation of the relation of the spleen to the red corpuscles is still wanting. The author reports a second case of **splenectomy**—in this instance for **malaria**. The patient was a woman, 34 years old. About 90 days after the operation she again had intermittent fever, which yielded to quinin. In her case there was a moderate hyperglobulia, 5,500,000, several years after the operation. The white corpuscles were not increased. A differential account gave 40% polynuclear cells, 1% large mononuclear, 47% small mononuclear, 2% transitional, and 10% eosinophile cells. [D.R.]

1. Concerning Functional Heart Diseases. HOCHHAUS.
2. The Selection of Suture Material. KRÖNIG.
3. Concerning Phloridzin Diabetes. A. SEELIG.
4. Subphrenic Abscess. O. KROHNE.
5. Are there some Genetic Relations Between General Neuroses and Appendicitis? O. SCHAUMANN.

1.—Hochhaus first gives a more or less general discussion of **functional cardiac disease**, stating as the chief symptoms first, subjective, consisting of a feeling of pressure or even of pain in the region of the heart with sensory symptoms elsewhere in the nervous system; and secondly, objective, consisting chiefly of consciousness of changes in the cardiac action. He has made a study of the blood-pressure with the instruments of Gärtner and Riva-Rocci in order to determine whether these show any characteristic changes. He found the pressure in 36 cases of cardiac neuro-

ses almost constantly high, varying usually between 160 and 190 mm. of mercury in men, and in women between 150 and 170; the normal is commonly between 100 and 160. Hochhaus admits that excitement in these nervous people is likely to raise the pressure considerably, but he has never drawn conclusions from the first examination. The result of repeated examination showed almost always that the pressure subsequently was 10 to 15 mm. lower than at the first examination. This increase in blood-pressure is not absolutely distinctive of **cardiac neuroses**, of course, but in most cases of organic disease the pressure will be found not more than 140 mm.; if the pressure is found constantly high it points toward a cardiac neuroses. A more important point is that if blood-pressure is constantly high in cardiac neuroses it points toward almost unavoidable ultimate damage to the heart and arteries because of this continued high pressure; several authors have already pointed out that arteriosclerosis is a common result of cardiac neuroses. The causes of increased pressure may be increased cardiac action, or abnormal contraction of the peripheral arteries; probably both are active, but in most cases Hochhaus thinks that the chief cause is increased energy of the cardiac action. He has strengthened this belief by observing these patients with the fluoroscope. He found that there was quick, energetic cardiac contraction, the shadow produced by the heart becoming suddenly decidedly smaller than is observed in normal hearts during contraction, hence indicating that the contraction was more complete. Hoffmann has stated that there is an abnormal movability of the heart in cardiac neurosis. Hochhaus has been unable to observe this. As to treatment he recommends small doses of digitalis, about ½ of a grain, in combination with quinin. [D.L.E.]

November 8, 1900. [26. Jahrg., No. 45.]

1. A Case of Aneurysm of the External Iliac Artery with Rupture and Subsequent Ligation of the Common Iliac Artery and Aorta. W. KÖRTE.
2. Bacteriology of the Lymph. CZAPLEWSKI.
3. Dermatitis from Primrose Poisoning. A. PIZA.
4. Selection of Suture Material. KRÖNIG.

1.—Körte found an **aneurysm of the right external iliac artery** in a young man, 29 years of age, robust, and otherwise healthy, with no specific history. The cause was supposed to be the effort in mountain climbing. Körte ligated the right common iliac with one catgut and one silk ligature; the patient reacted well from the operation with only slight symptoms, tympanites, hiccup, paralysis of the bowel, etc. In 3 days all had disappeared. The leg, which was pale, regained its normal color in about an hour. The tumor stopped pulsating but did not decrease in size, and 37 days afterward it still remained. Fearing a hematoma which would develop into an abscess, a small trocar was passed into it. A quantity of dark red blood escaped, followed by arterial bleeding, which could not be controlled. The **aorta** was then tied above the inferior mesenteric, but the patient never reacted from the shock. Stimulants and normal salt solution had no effect and death followed 1 hour afterwards. The failure to form a hard clot in the aneurysmal sac was due to the free anastomoses (1) the inferior epigastric and the internal mammary; (2) the circumflex iliac with the lumbar branches; (3) the superior and inferior mesenteric with the hemorrhoidal and pudendal arteries; (4) the spermatic with epigastric and hypogastric; (5) the vasa vasorum. The necropsy also showed that the common iliac had been obliterated by the first ligature. [W.S.N.]

2.—Czaplewski discusses the paper presented some time before by Nakanishi, in which the latter author described a **bacillus** as a constant finding in **vaccine pustules**. He claims in the first place that Nakanishi has misrepresented the statements made by Czaplewski concerning *Staphylococcus quadrigenus*, because the latter author never stated positively that the latter organism was the cause of vaccinia. He stated, however, that this organism can be found in fresh calf lymph. It can be found in sections made from the vaccine pustules from the first day on and always in increasing number, and it has been found possible by inoculating this organism to produce pocks and pustules in calves which when further inoculated into calves and children caused indubitable vaccinia. But he stated on the other hand that there were certain objections to the acceptance of the

staphylococcus as the cause of vaccinia. One point of importance is that this staphylococcus was found as a regular saprophyte on the skin of healthy calves, and for this reason and others it was decided that the positive results obtained in the transmission experiments were due merely to some form of stable infection which was transmitted in the experimental work. Czaplewski therefore decided that no etiologic importance could be given to *Staphylococcus quadrigeminus*, but he does consider that this staphylococcus is of importance in that it is a new variety of organism differing from *Staphylococcus aureus* and *Staphylococcus albus*. As to the bacillus described by Nakanishi, Czaplewski states that this bacillus has been repeatedly observed by other authors, and it is generally admitted that it belongs to the class of pseudodiphtheria bacilli and has nothing to do with the production of vaccinia. In a note Czaplewski states that Nakanishi has himself recently stated that the bacillus which he described has no etiologic relation to vaccinia. [D.L.E.]

3.—Piza directs the attention of the general profession to the fact that the **primrose** may cause a **serious dermatitis**. This fact is well recognized by dermatologists and most of his statements are derived from their previous writings. The chief symptoms produced are, general nervousness, sleeplessness, loss of appetite, some weakness, reddening of the skin, and the development of papules and vesicles. [D.L.E.]

6. Sympathetic Ear Diseases. RHESE.

1.—Koch states that at Ponape he made investigations of 79 children, and in no case were the characteristic **clinical signs of malaria** found, nor were the parasites seen in the blood; hence this region seemed to be free of **malaria**. There were in this region also but very few cases of yaws. In Seipan, 24 children and a number of adults with various affections were investigated, and parasites and clinical symptoms of malaria were always absent. It was decided, therefore, that in this region also malaria was absent. Yaws was frequent and Koch thinks that it is very often called syphilis, and that the general acceptance of the belief that syphilis is very common in the South Sea, and particularly in the German colonies, is largely due to confusing yaws with syphilis. In Seipan he observed a peculiar affection which reminded one of beriberi. It ran a course with fever and with permanent paralysis. One case with this affection showed a hemiplegia, and others a rheumatic condition of the joints and muscles. There was, however, no distinct case of beriberi. In Egypt, particularly in the region about Cairo, he considers that malaria is undoubtedly prevalent, since a number of cases were observed. [D.L.E.]

2.—Ulenhuth describes some very interesting results from the injection of **egg albumin** into rabbits, and the subsequent testing of their **blood serum** concerning its **influence upon solutions of albumin**. His results were as follows: Repeated intraperitoneal injection or intrastomachal ingestion of the albumin of hens' eggs produced some substance in the serum of rabbits so treated which, when the serum was added to a solution of hens' egg albumin caused either cloudiness or precipitate in the solution. The same occurred in a solution of albumin of pigeons' eggs. The serum of the rabbit treated with doves' egg albumin had the same influence noted above upon solutions of albumin from doves' eggs. This reaction with the serum occurred only with solutions of egg albumin, and not with solutions of various other forms of albumin. The delicacy of this test for egg albumin is much greater than that of ordinary chemical methods. It showed less than one part in 100,000. The serum could be heated to as high as 60° for over an hour without in any way interfering with the reaction. [D.L.E.]

3.—Waldvogel in determining the **freezing point of the blood** used the clinical method described by Drazer. It consists in placing a wide test tube in the freezing mixture, hanging in this test tube a narrower one which contains the fluid to be investigated, and in which also a narrow thermometer graduated to $\frac{1}{100}$ of a degree is so placed that it does not touch the sides of the tube. The blood was taken from the arm vein by means of a canula, then placed on ice for about 48 hours, and the serum pressed out and used in the test. The normal varied from 0.54 to 0.58. The most important part of his investigations was the observation that the highest freezing points were found in convalescents, the lowest in the fatal cases. Most of the cases with extremely low freezing points died. One is still living and free from fever, but is in extremely bad condition. The investigations of the urine for albumin and casts, the mental conditions, and other symptoms, indicated that uremia was not the cause of the high results obtained in most of these cases of typhoid, and Waldvogel believes that there is no good evidence that high values are found in uremia. He thinks uremia is to be attributed rather to the quality of the substances found in the blood than to the quantity; in other words, that it is not the accumulation of large amounts of poisonous matter in the blood, but the accumulation of very poisonous substances. His investigations of the freezing point of the urine, the amount of sodium chlorid in the urine, the amount of nitrogen, and the total amount of the urine also speaks decidedly against the possible belief that the high values were due to poor kidney function. The freezing point of the urine was about normal in all except one case. The diazo reaction was also tested. Waldvogel expresses himself as convinced that this reaction is of little or no value in diagnosis. There was no direct relation between the activity of the agglutination reaction, and the freezing point of the blood. The explanation of the high values for the freezing point of the blood was not to be found in the loss of water and thickening of the blood. The estimation of the salts of the blood showed that there was no definite increase in them, and the alkalinity was somewhat reduced, hence the salts were not increased. He believes that the increase was due to an increase in the albuminous bodies. The same thing has been observed in diphtheria antitoxin, and it is possible that the increase in albuminous bodies is really an increase in antitoxin; but this is an unsettled question, and Waldvogel does not insist that the increased values in the freezing point indicate an increased amount of antitoxin. [D.L.E.]

4.—Müller believes that **hydrogen dioxide** is one of the best solutions for **washing out a wound**; it cleans the wound of pus and detritus as well as destroys the bacteria by its antiseptic action. It is also a deodorizant and is itself odorless; when applied it causes no pain and these properties make it especially valuable. These conclusions have been reached both by its practical application and experiment; the latter consisted of different bacteria cultures being rendered sterile when mixed with hydrogen peroxid and these compared with control cultures and with other antiseptics. [W.S.N.]

5.—The theory put forward in a somewhat theoretical article is this: He admits the reflex origin of asthma, but he does not place the hyperesthetic zone in the terminal branches of the trigeminal nerve, but in the central nervous system; that is, the **hyperesthesia in cases of asthma is chiefly of a psychic character**. He admits the presence of other hyperesthetic areas, however, and his theory of asthma is chiefly that there is, owing to more or less stenosis in the nose or nasopharynx, or to chronic bronchitis, an almost unnoticed but practically constant shortness of breath, which is scarcely appreciated by the patient himself, but which excites an abnormal sensitiveness of one's appreciation of dyspnea. The onset of a little more swelling of the bronchial mucous membrane, of a slightly greater stenosis along the upper air-passages, the exposure to irritating dust, vapor, or other substances, and similar conditions, are sufficient to increase this half-unnoticed feeling of dyspnea to the point which brings on spasm of the bronchial tubes and asthma. The author lays great stress upon the importance of the local conditions, however, such as slight nasal stenosis, in causing asthmatic attacks through the production of this constant subconscious feeling of dyspnea, and he advises in all cases in which

there seems to be any stenosis in the nose, total or partial resection. [D.L.E.]

6.—Rhesé believes there is a low grade inflammation of the middle ear, which may be due to irritation from the trigeminal nerve or extension of inflammation from surrounding parts; great benefit will be noticed by **removing the hammer**; this allows the parts to rest and the inflammation usually subsides and the hearing improves. In cases of long standing, when both ears are affected and the hearing is very defective, this operation is not to be recommended. [W.S.N.]

Centralblatt für innere Medicin.

November 10, 1900. [24. Jahrg., No. 45]

1. Eupyrin. OVERLACH.

1.—Overlach was led to the production of **eupyrin** by his search for an antipyretic that had no depressing effect upon the circulation. Eupyrin is the ethyl-carbonate of vanillum in combination with P-phetidin. It is said to be without unpleasant taste or odor; to have definite antipyretic effects without any depressing influence; contrary to phenacetin it does not produce any spectral evidence of the presence of methemoglobin except when given in very large doses, and even then the spectrum of methemoglobin is exceedingly weak. It has decidedly stimulating instead of depressing effects. The patients have some tendency to habituate themselves to the use of the drug, however, because of the pleasant stimulation which they themselves observe. It does not seem to have any special value as an antineuralgic. It is, however, a useful antipyretic, and is most important in children and old people as a mild and apparently non-poisonous antipyretic. [D.L.E.]

November 17, 1900. [24. Jahrg., No. 46]

1. Bacteriological Investigations of the Blood in Pneumonia. A. PROCHASKA.

1.—The investigations were carried out by making direct preparations from the blood by cultures and animal experiments. Prochaska found that by the use of small quantities of blood the results were very variable, hence he used larger amounts, taking the blood from an arm vein with a syringe, and inoculating 4 or 5 cc. on bouillon. As controls he inoculated a few drops on bouillon and on agar slants. The results were practically constant in the cultures in which large amounts were used, but were variable in the other cases. Ten cases are reported which were of moderate severity on the average; 6 of them recovered without any marked signs of severe infection, while 4 ended in death. In all of these cases the large amount of blood gave regularly cultures of the pneumococci. Prochaska thinks that the use of large amounts of blood will practically result regularly in the discovery of the pneumococcus during life. [D.L.E.]

November 24, 1900. [24. Jahrg., No. 47.]

1. The Effect of the Distillate of Coffee and Tea Upon the Respiration and the Heart. C. BINZ.

1.—There is a brief review of the previous literature upon this subject, then a report of a series of experiments, the results of which are summarized as follows: The caffeine-free distillate of roasted coffee increased the respiration, particularly after abstinence from food. This was not of long duration, and was the result of an increase in the number of respirations, not in their amplitude. Some effect was seen even in dogs who had been completely paralyzed with alcohol. There was some slight muscular irritability and slight psychic excitement after taking the distillate. The frequency of the pulse was not changed. The distillate of a good Chinese tea gave the same results, though less marked. These results are against the statement of Lehmann that the aromatic substances contained in a coffee distillate have no notable effect upon the brain or muscles even in large doses. As a general result Binz states that we may consider that the chief effect of coffee and tea is due to caffeine. He refers to legends which indicate the effect of coffee and tea. One story is that a poor dervish in the valley of Yemen frequently noticed that his goats were particularly lively on

their homeward way in the evening. He saw that they ate the leaves, blossoms and branches of a plant, and when he himself took this he found that he became so happy that his neighbors considered that he was drunk with wine. This he explained to them was an error, and showed them the plant, and it was then clear to them all that Allah had given coffee to believers to guard them from the dangerous juice of the grape. Another story stated that a friar having learned that the goats who ate coffee leaves were exceedingly lively gave the leaves and fruit to his monks with the result that while the monks had previously been lazy and sleepy in their nightly duties they became active and happy in the discharge of them. A third story was that a priest of Buddha went from Japan to China in order to spread his religion. Since sleep overtook him at night he was unable to carry on his work excepting during the day. In his religious frenzy he cut off his eyelids and threw them from him. Where they fell upon the earth there sprang up the tea plant, and thus the religious frenzy of the priest provided for believers a goodly drink. [D.L.E.]

Centralblatt für Gynäkologie.

November 3, 1900. [24. Jahrg., No. 44.]

1. The Pathology of the Placenta. E. MARTIN.
2. Upon Spontaneous Gangrene of the Bone in the Puerperium. E. WORMSER.
3. Upon Treatment of Puerperal Fever. VICTOR STEINER.

1.—Martin, in the spring of 1899, began his examinations to prove the existence of **syncytical growths in the eclamptic placenta**, and he now confirms the opinion of Bulius and Fink that these growths begin about the seventh month of pregnancy. Their frequency and strength vary, often being small in eclamptic and nephritic placenta. He concludes, therefore, that these syncytical growths are typical neither of eclampsia nor nephritis, but are the normal condition at the end of pregnancy. [W.K.]

2.—Wormser gives a detailed report of a case of gangrene of the bone of the foot during the puerperium, occurring in a healthy woman, aged 23. Six days after a normal delivery, she complained of pain in the left leg, which on the twelfth day became localized in the left foot. The disease advanced rapidly, and on the thirty-ninth day the foot was amputated, with recovery of the patient. The direct cause in this case seemed to be the entire cessation of circulation, owing to an extended thrombus in the veins, probably due to an embolism in the arteria tibialis antica. A symptomless endocarditis had developed during the puerperium, which must come into consideration as a cause of the embolism. Wormser quotes a number of cases of this rare condition collected from literature. One characteristic sign is a dry burning, though in cases of general sepsis with putrefaction of the thrombus there comes a moist gangrene. Other signs are severe pain and the presence of dead tissue, with, in most cases, a distinct demarcation. Accompanying symptoms are fever and rapid pulse, due partially to the thrombosis or endocarditis, and partly to the absorption of the decaying tissue. The diagnosis is not difficult, and rests upon the discoloration and coldness of the skin, loss of sensibility, etc. The prognosis is difficult. To foresee the result is as impossible as to hinder it. It remains for us only, as soon as signs of obstructed circulation are evident, to secure, as far as possible, conditions favorable to circulation, the accomplishment of venous reflux, and increase of heart action. Perhaps the use of leeches would be justified in order to prevent further formation of blood-clot. [W.K.]

3.—Steiner emphasizes the fact that in the hospital at Hagenau, in cases of puerperal fever, Bidert before all requires the cleansing of vagina and uterus through irrigation and disinfection; of the former with lysol solution (1:1000), the latter by means of a thick male catheter with 1% kresol on account of its nonpoisonous properties and transparency. When any abdominal inflammation is present an icebag should be used. It is also considered of extreme importance to keep the intestines in a quiet condition if there are signs of peritoneal inflammation due to pain in uterus or adjacent organs or an existing parametritis or perimetritis; and he refers to a case in which after 8 days' fever the temperature at once sank to normal when

the evacuation of the bowels ceased and a rapid recovery followed. He reports 2 cases in which serum was used in the treatment of puerperal fever, but reaches no definite conclusion as to its value. [W.K.]

Neurologisches Centralblatt.

November 1, 1900. [19. Jahrg., No. 21.]

1. Further Communications Upon the Electric Irritability of the Spinal Cord in Decapitated Persons. A. HOCHÉ.
2. Progressive Hemiatrophy of the Face. A. HOFFMANN.
3. The Conduction of Sound by the Cranial Bones in Disease of the Brain and its Membranes. F. WANNER and H. GUDDEN.

1.—As a result of the active interest and participation of the authorities, Hoché was able to study the **spinal cords** of 2 men in less than 3 minutes after their **decapitation**. These, in connection with 2 cases already studied, have led to various interesting results. The first patient for the first 8 minutes of the investigation showed active, quick, muscular contractions. If the electrodes were placed near the anterior columns, the arm on the same side moved; if near its posterior columns, both arms moved; if very strong currents were employed, and the electrodes placed near the anterior columns, both arms moved, and the leg on the same side. At the end of 8 minutes the contractions became slow and worm-like, resembling those of muscular degeneration; nevertheless, if the needle was plunged into the tissue for a distance of $\frac{1}{2}$ to 1 cm. so that portions of the spinal cord not exposed to the air were touched, the contractions again became active. The second case was obtained 3 minutes after execution, and practically the same phenomenon observed. The diminution in the activity in the exposed cross-section occurred 15 minutes after death. If the left posterior root was stimulated, the left arm moved; increase in the amount of electricity caused movement also of the right arm, showing that the first phenomenon was not due merely to fibers passing directly from the posterior root to the anterior horn on the same side. Nor can the fact be ascribed to the irritation of the fibers, because if such were the case the limbs would be more frequently stimulated. Hoché concludes that the human spinal cord maintains its vitality for about $\frac{1}{2}$ of an hour after decapitation; that the movements were due to the stimulation of the internal spinal portions of the roots. As the stimulation only involves the segments to which the electrode is applied, it will be possible to obtain quite accurate results regarding the motor innervation of the cervical segments. He notes, also, that in both cases the patellar reflexes were lost immediately after decapitation; unfortunately it had not been possible to determine their presence during life, nor was it possible to exclude the influence of shock. [J.S.]

2.—The first patient was a boy who, at the age of 5, had struck the right cheek against the edge of a paving-stone. A few months later, the skin in this region became pale, and this area gradually extended. The skin became thinner, and the whole **right side of the face developed less rapidly** than the other. There were no other disturbances; the tongue was not atrophied, and the pharyngeal reflexes were normal. As a result of the prolonged action of the anode of the galvanic current ($\frac{1}{2}$ hour and more), considerable improvement has occurred. The second case, a woman of 42, had suffered for 17 years with severe attacks of facial neuralgia. Only within the last 6 months has any change been observable in the face. The left side has become smaller, the skin paler, and the bones more prominent. The 2 cases are interesting because in the first the traumatic involvement is apparently very clear, and in the second the fact that the neuralgic pains preceded the atrophy for such a long period, is sufficient proof that they were not secondary, and that the disease is rather a trophoneurosis than a form of skin disease. [J.S.]

3.—Wanner and Gudden continue their description of the results of investigations on patients. They conclude as follows: In cases of **doubtful diseases of the central nervous system**, a distinct shortening of bone conduction without the characteristic accompanying symptoms of disturbance of the hearing, even when normal hearing persists, it is justifiable to diagnose **organic changes in the skull**. This symptom is more valuable because it is practi-

cally impossible for a person to simulate it. Unfortunately the presence of normal bone contraction does not justify the exclusion of organic disease, it is probable that some alteration takes place in the bone, which allows the sound-waves to become more rapidly dissipated. Experimentally it has been found that hard substances, such as dry, macerated bone, do not diminish the period of contraction in normal persons, but soft substances do diminish it very considerably. Sound may also be conducted from one living head to another until 6 have been placed in line. In old age a certain amount of diminution in bone conduction occurs. [J.S.]

Revue de Médecine.

August 10, 1900. [20me Année, No. 8.]

1. Sadism Produced by a Bull-Fight. CH. FÉRÉ.
2. On the Hereditary Syphilitic Diseases of the Spinal Cord in Newborn Children and in Infants at the Breast. DE PÉTERS.
3. Persistence of the Ductus Arteriosus. G. GÉRARD.
4. Acute Dysenteric Hepatitis and Its Treatment by Bleeding the Liver. PAUL REMLINGER.

2.—De Péters has studied the **hereditary syphilitic diseases of the spinal cord in newborn children and in nursing-infants**. He reports 5 illustrative cases. As a result of his studies he concludes that the fact of the participation of the spinal cord in newborn children and of infants at the breast in the hereditary syphilitic process is equal to that of the other tissues has not only a considerable theoretic significance but also much practical importance. The paralysis that results from this specific affection of the spinal cord present a new pathologic symptom that in itself gives the possibility of diagnosing syphilis in cases that present nothing else suspicious, either in the way of clinical signs or in the facts obtained from the history, and where all the classical symptoms of syphilis are wanting. The floating motion "*flossenstellung*" of the hands, an isolated paralysis of the muscles of the shoulder-girdle, an isolated paralysis of the leg, an isolated contracture of one group of muscles; for example, the iliopsoas muscle or the muscles of the neck, coexisting with paralysis in other muscles, or even the symptom of Dejerine-Klumpke itself have the same decisive importance for therapeutics that a palmar psoriasis, a cutaneous syphilid, or a condylomatous condition of the skin or of the mucous membranes formerly had. Certainly in the cases in which one of the stigmata that have just been enumerated exists, the nervous symptoms have no especial diagnostic significance, but these cases are far from being the most frequent. It is more difficult to prepare a clear table of the disease and to decide on the necessary treatment when cutaneous eruptions and affections of the mucous membranes are discrete or wanting and when the history presents nothing suspicious. In such cases the paralyzes in question have great diagnostic value. [J.M.S.]

4.—Remlinger contributes a paper on **acute hepatitis following dysentery**. He reports 4 cases. In the first case the patient was a young soldier who contracted dysentery a short time after his arrival in Tunis. As a result of this attack the patient had a tendency to diarrhea, and 18 months later he was taken with symptoms of acute suppurative hepatitis. Exploratory puncture did not discover any pus, although several spoonfuls of blood issued from the point of puncture. The next day the condition was much better, and convalescence was rapidly accomplished. In the second case, the patient was a young man without antecedent history, who was suddenly seized, in the course of a dysenteriform diarrhea that he had neglected for a month, with violent hepatic pain that radiated to the left shoulder. The liver was markedly increased in volume. There was fever, and the condition looked very much like that of suppurative hepatitis. Puncture, however, did not show the presence of pus, although a small quantity of blood was withdrawn by the needle. The next day a very marked amelioration of the symptoms was noted, which, in the following days, went on to complete cure; although the convalescence was interrupted by a right-sided serous pleuritis. The third case was that of a man of 39, who entered the hospital with all the signs of extremely grave hepatitis following an attack of dysentery. The symptoms were ameliorated by bleeding

from the liver, but the patient died from an unknown cause 25 days after leaving the hospital. The fourth patient was a man of 35, who had had dysentery that was followed by diarrhea and repeated attacks of hepatic pain which radiated to the right shoulder. The author saw him in one of his attacks. As a result of his studies, Remlinger concludes that dysentery is capable of producing two kinds of complicating lesions in the liver—acute hepatitis and abscess. The differential diagnosis of these two affections is possible, although difficult. In obscure cases, puncture will remove the doubts. Puncture is the first step in the surgical treatment of an abscess, and if the condition is one of acute hepatitis, it is the first step in the **bleeding of the liver**. It is without danger and without inconvenience of any sort. Whether the bleeding of the liver acts as relieving congestion simply, or in subtracting from the gland a certain quantity of microorganisms and in favoring leukocytosis, it is followed, in the case of acute hepatitis, by an amelioration of the local and a general condition so rapid, and soon by a cure so complete that any other therapeutic procedure cannot be compared to it. [J M S.]

II Policlinico.

(Sezione Pratica.)

November 3, 1900. [Anno vii, Fasc. 1.]

1. On the Cocainizing of the Spinal Cord. G. DOMENICHINI.
2. Transactions of Congresses.
3. A Case of Cerebral Tumor. SALVOLINI.

1.—An account of 3 cases, 2 of colporrhaphy and 1 of resection of the saphena vein, operated on by Domenichini by **Bier's method**. Advantages are claimed for the injection of the cocaine solution with an admixture of morphia and trinitrin, the patient lying prone with a support to raise the lumbar region. [G S B]

2.—At the Congress of the Italian Surgical Society held at Rome on the 27th to the 30th of October, Biondi described the results of 8 operations on the **vertebral column**, of which 4 were for tuberculosis, 3 for fracture, and 1 for dislocation. Six of the cases recovered, 4 completely, 2 partially, and 2 had recurrence of the disease. Caccarelli, speaking of vertebral tuberculosis, deprecated operative treatment as tending to weaken the vertebral column and recommended rest rather than massage and movements, condemning likewise Calot's method as irrational and dangerous. Durante referred to 2 cases of operation for cerebral tumor, one involving the right anterior frontal lobe, the other pressing upon the right postrolandic region. The clinical manifestations in the first case showed the importance of the anterior frontal lobes in relation to the moral character, the symptoms in the other proved that the centers of sensibility are in great part situated in the postrolandic region. Roncali had examined the tumor, a fibrosarcoma, removed from Durante's second case. It contained blastomycetes in the form of Russell's bodies, so situated in the neoplasm as to indicate a casual relationship between them and the growth. Bastianelli, Durante, and others expressed scepticism as to their parasitic nature, holding that the proofs hitherto supplied have not been demonstrative. At the Congress of the Italian Obstetrical and Gynecological Society, held at Naples on the 20th to the 23d of October, 1900, Cosentino noted the rarity of **inversion of uterus in labor**, ascribing its occurrence as due mostly to imprudent efforts to remove the placenta. In nonpuerperal conditions it follows the expulsion of tumors. In recording various methods of treatment by taxis and by surgical intervention, he referred to his own method of gentle dilation of the cervix through the opened abdomen, and those of Kustner and of Piccoli by incision of the posterior wall of the uterus and reduction of the uterus by the vaginal operation. [G S B]

3.—For two or three months the patient had suffered from headache associated with general weakness; later his moral character had changed, the pulse was slow, and ptosis of the left upper eyelid, paralysis of the left lower side of the face, clonic spasms in the left arm, efforts at vomiting, and paresis and then paralysis of the tongue developed. A fortnight after admission coma supervened and death. The syndrome indicated a localization of the lesion to lower part of the right pararolandic region, and, in fact, at the autopsy a **gliosarcoma** was found in the white matter in that situation. [G S B]

November 10, 1900. [Anno vii, Fasc. 2.]

1. Histogenetic Researches on Primary Epitheliomata and Endotheliomata of the Liver. A. PEPERE.
2. On the Treatment of Obstinate Neuritis of the Great Sciatic Nerve by Stretching. D. B. RONCALI.
3. Importance of Raw Vegetables in the Diffusion of Infection and Parasitic Diseases. G. CERESOLE.
4. Transactions of Congresses.

1.—Peperé has examined 10 cases of **primary tumors of the liver**, 6 epitheliomata and 4 endotheliomata. He enumerates their various distinguishing characters both clinical and histological, and tabulates a series of conclusions regarding them founded upon his observations. One striking difference was the presence of hepatic cirrhosis in epithelioma and its absence in endothelioma. What has hitherto been described as medullary or soft cancer of the liver he holds to be in reality endothelial sarcomata. One of the cases, he thinks, confirms the theory of the congenital origin of solitary adenomata of the liver. [G S B]

2.—Roncali reviews the history of the operation and relates a case of **sciatica of rheumatic origin** of 10 years' standing in a peasant, 30 years of age, in which he treated the disease successfully by stretching. He counsels a resort to this measure in the sciatic neuralgia of various origins—traumatic, rheumatic, and infective—whenever it resists ordinary treatment; in spasms and paralyses of traumatic origin it is less successful; whilst in epilepsy, tabes, tetanus, myelosclerosis, and transverse myelitis, its benefit is nil or doubtful. In tetanus he does not consider it a measure to be recommended. [G S B]

3.—A very interesting article illustrating the **dangers of eating salads** in Italian cities. The vegetables which were examined were of the varieties so largely consumed in the raw state by the poorer classes in Italy and were bought on the market at Padua. After being washed in the same way as if for domestic use, they were subjected by Ceresole to a direct microscopic and to a bacteriologic examination. Under the microscope some 52 species of various animalculæ were recognized, including *Am-ba coli*, *Balanitidum coli*, *Isotrica prostoma*, and *Anguillula stercoralis*, together with eggs of different varieties of worms, some of them pathogenic, namely, *Tania echinococcus*, *Oxyuris vermicularis*, *Ascaris lumbricoides*, *Tricocephalus dispar*, and *Anchylostoma duodenalis*. Bacteriologically myriads of forms were found, mostly harmless, but among them were *B. coli communis*, a bacillus with all the characters of *B. typhosus*, *B. septicus*, and *B. tetani*. The probable sources of these impurities are indicated and the danger of their spreading disease pointed out. For disinfection of the vegetables it is said to be sufficient to soak them for half an hour in a 3% solution of tartaric acid. [G S B]

4.—At the third sitting of the Congress of the Italian Surgical Society (October 28, 1900) Nannotti recalled experimental researches on the exclusion of the colon, complete and incomplete, made by him on dogs, and described 2 cases in the human subject where he had confirmed the favorable results then obtained. In one case of enterocolitis an ileo-rectostomy was performed by laterolateral anastomosis, and a perfect recovery resulted. Ottaviano communicated a case of actinomycosis of the appendix, Gangitano one of terminal colapexy, and Jacobelli a paper on the possibility of the rellux of urine from the urinary bladder into the ureters.

At the Congress of Italian Obstetrical and Gynecological Society (Naples, 20-23 October, 1900), Mangiagalli stated his experience of the method of combining vaginal hysterectomy with colporrhaphy for the cure of uterovaginal prolapse, describing the technic of the operation as practised by surgeons from Fritsch onwards, as well as his own modification of it. Both procedures, he thinks, should be carried out at one sitting. He has seen some of his cases operated upon 5 years ago, and the results have been excellent. [G S B]

Hernia into the Foramen of Winslow.—A case of this nature is reported from Australia. The gut was reduced and a double enterotomy performed. An artificial anus has formed at the opening made in the cecum and this has been left permanent at the request of the patient, to act as a safety valve in case of recurrence of obstruction.

Practical Therapeutics.

Under the charge of

A. A. STEVENS, A.M., M.D.

On the Use and Abuse of Lavage.—Musser (*Therapeutic Gazette*, November 15, 1900), believes that not 5% of the cases of gastric disease or of patients suffering from symptoms suggestive of gastric disease that are under his care have required lavage in their treatment. He employs lavage in cases of atonic dilation, when retention is extreme; in cases of organic pyloric obstruction; in cases of gastric neurasthenia and in certain cases of hysteria; in some cases of chronic gastritis with subacidity. This limits its practice to a small number of cases only. In some cases of hysteria he employs lavage once a week or ten days for reasons readily appreciated. In his earlier practice, the author states that he employed lavage more frequently, but he has found that he can obtain as good results with other means. He can do more with a carefully regulated diet, with massage, physical culture, outdoor life, mental occupation and cold baths than with local gastric treatment. The most useful mechanical gastric management in selected cases is a properly fitting abdominal belt. The truth of the matter is that most so-called gastric cases are not of stomach origin. The nervous system, the blood, the general and local musculature are at fault. Hence, more gastric cases are cured by iron than by pepsin; by nuxvomica than by specific aids to digestion. When the author employs lavage he does it himself or has a medical man do it at stated intervals. To allow patients to do it soon develops in them a habit, which cannot be too strongly condemned.

Thyroid and Ovarian Extracts in Gynecologic Practice.—E. E. Montgomery (*International Medical Magazine*, November, 1900) states that he has never seen the slightest influence in any way through the use of ovarian extract. Thyroid extract he has found especially valuable in the treatment of myxedema, obesity, and particularly in the treatment of some forms of sterility. That it has a marked influence upon the mucous membrane of the uterus is evident from its effect upon uterine hemorrhage. In cases of hemorrhage from nonmalignant conditions, near the climacteric, thyroid extract is especially efficacious. It also has an influence in arresting the growth and promoting the absorption of fibroid growths. The author was led to employ the drug in the treatment of sterility after having seen some cases in which women became pregnant after its use for the treatment of obesity. One patient lost 70 pounds under the use of the drug and immediately became pregnant. In another patient who had never menstruated, been married 8 years, the surgeon found that she had an enlarged ovary, removed it and punctured a number of cysts in the other ovary. Following this operation she began to menstruate regularly. She was desirous to have children, and after menstruating for a year, she began the use of thyroid extract and became pregnant. She gave birth to a child at full term and is again pregnant.

Treatment of Aneurysm of the Aorta.—In the Section of Therapeutics at the recent International Congress of Medicine, Golubinin, of Moscow (*Medical Age*), said he had employed in 8 cases the method of treating aortic aneurysms by injection of gelatinized serum recommended by Lance-reaux and Paulesco. The number of injections varied, according to the case, from 2 to 15. Of the 8 patients 4 died in a short time, and the other 4 were lost sight of; in 3 of the cases belonging to the latter group the injections produced no effect. In the remaining one they were followed by slight improvement in the subjective symptoms without modification of the objective signs. Golubinin had come to the conclusion that the method did not fulfil the expectations that had been founded on it. Huchard said that in the treatment of aortic aneurysms it is a mistake to allow oneself to be hypnotized by the changes to be brought about in the contents of the sac—that is to say, in the blood—and to take no account of the containing structure. The method of gelatinized injections, which is useful, although insufficient, is open to this criticism. To complete its action, especially in persons

with large heart and increased arterial tension—they are almost always at the same time subjects of Bright's disease—medicaments should be chosen which diminish arterial tension, such as potassium iodid, trinitrin, nitrite of amyl, and especially tetranitrate of ethylol, or tetranitrol, which Huchard has now used for a considerable time, and which, as compared with trinitrin, has the advantage of a more durable action. Moreover, an essential point is to supervise the diet, not in regard to quantity, as in Valsalva's method, but in regard to quality. Meat, which holds too large a place in our food, contains toxins which have an excessively powerful vasoconstrictor action. The best treatment of aortic aneurysm is still absolute milk diet regularly adhered to.

Arsenical Sodium Phosphate.—Tichborne (*Medical Press and Circular*, June 11, 1900) states that it is difficult to find a sample of sodium phosphate that is not contaminated with arsenic. This arsenic does readily come down as a sulphide, and many specimens, if hurriedly tested, might appear as only slightly impure, whilst in reality they may be loaded with arsenic. The author purchased specimens of sodium phosphate in several important shops of Dublin, and not one of them was free from arsenic. Three of them showed respectively .033%, .024% and .028% of arsenous acid. In 2 samples since obtained there was still a higher percentage of arsenic. Calculating the maximum dose of sodium phosphate at $\frac{1}{2}$ ounce and arsenate of sodium as $\frac{1}{10}$ grain, it would appear that the most arsenical of the samples would contain in a maximum dose .134 grain of arsenate of sodium, or .034 grain in excess of the maximum. The author holds that only a salt should be used for medicinal purposes that is made by the interaction of phosphoric acid and pure sodium carbonate.

Perforation in Typhoid Fever from an Operative Standpoint.—G. G. Davis (*American Journal of Surgery and Gynecology*, September, 1900) reports 3 cases of typhoid fever operated upon for perforation peritonitis. The first patient had mild peritonitis, but no perforation, and recovery followed the operation. The second patient had a perforation on the forty-fifth day of his disease, and operation 10½ hours after the first symptom appeared was followed by recovery. The third patient had 2 perforations, and died 36 hours after the operation. The author believes that decided and sudden increase of abdominal pain with abrupt fall of temperature is diagnostic of perforation. Leukocytosis is confirmatory. Dulness in the right iliac region is not to be expected. It is not necessary to operate before perforation occurs, but it is necessary to operate before collapse is marked. Typhoid patients, when not in collapse, bear operation much better than was formerly supposed. Washing out the abdominal cavity with hot normal salt-solution, even if no perforation is present, seems to improve the condition at the time of operation, and favorably influences the course of the disease. Operation should be done as soon as the diagnosis of perforation is made.

Gastroenterostomy.—Carless (*Practitioner*, November, 1900) states that this operation may be advisably recommended under the following conditions: 1. When a patient with gastric ulcer has been carefully dieted and given every chance to recover, and yet the symptoms persist. 2. It may be utilized in the treatment of hemorrhage, in connection with gastric ulcer, which occurs either as an acute or as a chronic complication. 3. It is probably the best operation in all cases of pyloric stenosis due to gastric ulcer, and possibly the only feasible proceeding when stenosis of that orifice arises from extrinsic causes, such as the contraction of adhesions formed in connection with an inflamed gallbladder. 4. In pyloric cancer the same limitations are frequently present, the growth having early contracted adhesions to surrounding parts. 5. There are not a few cases of atonic dilation that are best treated by gastroenterostomy, though not until a thorough course of lavage and medicinal treatment has been undertaken. 6. In the condition known as hyperchlorhydria, or gastric succorhea, in which the patient is tormented with acid eructations and heartburn, to say nothing of pain and distention, the rapid emptying of the viscus is most desirable, and in no way can this be better accomplished than by the formation of an artificial opening in the jejunum.

Nephritis of Scarlet Fever.—Kemp (*Archives of Pediatrics*, July, 1900) recommends the use of oxygen inhalations, because they stimulate the heart and aid in the elimination of toxins. Another useful measure is enteroclysis, using a saline solution (110° to 120°F.) for 15 to 20 minutes at a time as often as 2 or 4 times a day. Experience shows that 3 to 5 times as much urine is secreted as the quantity of saline solution introduced. Warm carbonated baths (98° to 100°F.) are also useful.

Myrtol in Affections of the Respiratory Tract.—S. Solis-Cohen (*Merck's Archives*, November, 1900) states that the action of this drug is much like that of its congeners of the terebinthinate and balsamic groups. It is an oily liquid, of slightly yellow tint, pungent taste, and characteristic odor. It is eliminated chiefly by the mucous membrane of the respiratory and genitourinary tracts. The author's experience with myrtol has been limited to affections of the bronchi and lungs. He has had excellent results in some cases, and failure in others. The happiest results were in obstinate cases of bronchorrhea, dilated bronchi, fibroid phthisis, and bronchitic asthma. In some cases of asthma in which the paroxysms seemed to have been brought about by the effort to dislodge tenacious secretions, the use of myrtol seemed to increase the ease of expectoration, while later diminishing the frequency of expectoration and lessening the quantity of sputum. In fetid expectoration it seemed to diminish secretion. Eichhorst has used it with satisfaction in pulmonary gangrene. The author does not contend that myrtol is a miracle-working substance, but one marked in its influence in checking useless, annoying, unproductive cough. In his experience myrtol never tended to produce strangury. The dose is 5 to 15 minims, given from 2 to 5 times in 24 hours. When uncombined it may be given in emulsion, or dropped upon sugar, or placed in capsules, and if given in capsules it is well to have the patient take a little milk afterwards. It may be used likewise for inhalation.

Pichi.—Aronson (*Physician and Surgeon*, August, 1900) states that the drug is very efficient in hemorrhage from the kidney or bladder, in prostatitis, in seminal vesiculitis, and in the subsidiary stages of orchitis and epididymitis in combination with potassium iodid. In subacute urethritis he has used the following combination with gratifying results:

R.—Fluid extract of pichi.....4 drams.
Potassium citrate.....3 drams.
Tincture of hyoscyamus2 drams.
Spirit of nitrous ether.....3 drams.
Elixir of orange to make2 ounces.
One teaspoonful in water one and a half hours after meals.

The Therapeutics and Hygiene of Obesity.—Dechamps (*Treatment*, November, 1900) at the Congress of Medicine, 1900, stated that the treatment of obesity should not have for its end merely a temporary reduction in the weight of the patient, but attention should be given to a radical change in metabolism, whereby a proper balance between receipt and expenditure should be maintained. The effects of diet, temperature, and muscular exercise were the most important, and their regulation was the basis of treatment. The regime imposed upon the subjects of obesity should always be sufficient to satisfy and to assure the soundness of the gastrointestinal functions. The best dietary is one in which vegetables predominate. For beverage, pure or slightly alkaline water should alone be taken, and that never in excess of what is required to satisfy thirst. The chief means of reducing weight is the employment of hot baths at a temperature rather above that of the body, and lasting one to two hours. Static electricity is useful in assisting the training of the cardiovascular system, and in favoring organic combustion. Muscular exercise requires to be carefully regulated, and should be kept within limits short of producing fatigue.

Treatment of Tuberculous Peritonitis by Puncture, followed by Lavage with Sterilized Hot Water.—According to *Treatment*, November, 1900, Baylac stated at the Congress of Medicine, 1900, that the usual mildness of the ascitic form of tuberculous peritonitis, its frequent cure after laparotomy, and the many instances in surgery of the efficacy of hot water, gave him the idea of treating this affection by puncture, followed by lavage with sterilized water

at a temperature of 45° C. Lavage, without free opening of the peritoneal cavity, secures to the patient nearly all the advantages of laparotomy without exposing him to the dangers inseparable from the latter proceeding. The injection, also, of antiseptic liquids into the cavity of the peritoneum is not always free from peril. With sterilized hot water there is no accident to fear, no intoxication possible. Plain hot water appears to be as effective as the divers antiseptic solutions sometimes employed; and it puts the serous membrane, freed from its septic lining, in the most favorable condition for healing. Baylac has so treated 8 cases of ascitic tuberculous peritonitis; 5 times the cure was complete, in 3 others there was only temporary improvement. In the 3 last cases, certainly, the lavage was only practised after previous interference, such as punctures and laparotomy, so that the peritoneum had already lost its extreme delicacy, and could not be sufficiently affected by the hot water. The author considered sterilized water raised to a temperature of 45° C. an excellent agent for influencing the peritoneum in tuberculous inflammation, having these advantages: (1) in clearing the cavity of ascitic liquid, "a veritable culture bouillon in which the microorganisms thrive;" (2) in bringing about an increase in the number of leukocytes; (3) in increasing the activity of leukocytes and diminishing the virulence of Koch's bacillus.

Treatment of Locomotor Ataxia.—Allan McLane Hamilton (*Montreal Medical Journal*, October, 1900) states that the experience of many years convinces him that most tabetics are favorable subjects for "expectant attention," and clutch at any straw that may be thrown to them, and say they feel better for a time. In the disease known as pseudotabes in which there is often a somewhat rapid posterior spinal deposit or acute pathologic progress, enormous doses of iodid are useful, but in more advanced or slowly developing tabes the author believes this drug to be worthless. Looking back over a number of years he finds that the most good has been accomplished in the cases in which little or no medicine has been given, but which have been managed by *absolute rest*, occasionally by the *suspension treatment*, and, finally, by the systematic and persistent *cauterizing of the back*. So prompt have been the benefits of rest that, when possible, the patient should be ordered to his bed, or when this is impossible, to be completely inactive. No agent can be relied upon to relieve pain but opium or its alkaloid, but in some cases phenacetin, antipyrin, or bromate of phenol (10 grains every 2 hours) prove useful. The method of de la Tourette is recommended. This neurologist gives from 20 to 30 grains of phenacetin in 24 hours (in 8 grain doses), combining it, in the event of violent pain, with laudanum (10 drop.). In the gastric crises, sulfuric ether, either as Hoffmann's anodyne or in pearl form, or the spirits of chloroform, will often break up a paroxysm of pain. For many years the author has employed suspension in those cases in which there was no optic-nerve atrophy and no symptoms indicating coarse disease, and believes that it is worthy of careful trial. The actual cautery has, perhaps, proved of the greatest use, not only for the relief of pain in the largest number of cases, but it has a revulsive effect of its own, the exact nature of which cannot be determined. Certainly its application over areas of nervous distribution, which are the seat of pain, and where a kind of neuritis sometimes exists, is to be recommended. In many apparently intractable cases, the author has been in the habit of using it once or twice a week over the spinal column, and so often has a decided and lasting improvement taken place, that he unhesitatingly recommends it as a routine agent.

Empyema in Children.—Crandall (*International Medical Magazine*, October, 1900) states that aspiration and other temporizing methods of treatment are absolutely futile. Free incision with drainage is universally regarded as the only efficient treatment. Differences of opinion are confined chiefly to the extent of operation required. If performed early, simple incision has proved, in the experience of many competent operators, a perfectly efficient means of effecting a cure. If performed late, ribs should certainly be excised. The incision should be free; the drainage tube should be of good size; the cavity should not be irrigated; and every effort should be made to keep the wound in an aseptic condition.

ROTARY LATERAL CURVATURE AND POTT'S DISEASE OF THE SPINE: THEIR DIAGNOSES AND TREATMENT.

By A. M. PHELPS, A.M., M.D.,

AND

D. W. MANTON, M.D.,

of New York, N.Y.

WITH the possible exception of the treatment of appendicitis, there is probably not in all medical literature any topic on which our profession has held as many different and diametrically opposed opinions as has been the case with rotary lateral curvature and tuberculosis of the spine. Within the memory of men yet young, certain members of the profession in this country, as well as across the water, have claimed it to be possible to cure cases of later curvature of the spine after extensive bone changes had taken place. Nor is it more difficult to find writings in which all cases with marked kyphosis, even rapidly increasing, attended or unattended with abscess, were classed indiscriminately as "Pott's disease."

It is scarcely necessary for me to say here that these views are not now endorsed by representative surgeons. New ideas, however, even when sustained by unlimited pathologic and bacteriologic research and clinical experience are often slow of adoption, and it is on this account that I purpose here to briefly differentiate not only in the etiology and pathology, but also in the treatment of these two time-honored bugbears of the profession.

Not all cases supposed to be such are always Pott's disease. Deformity similar to that caused by tuberculosis of the spine is seen following absorption from the peyerian patches of the intestines in typhoid fever. This condition would be readily discovered in connection with a history of other typhoid symptoms. Another rare affection of the spine resulting in kyphosis is caused

by the inoculation of the germs of actinomycosis. We also recognize another condition closely simulating tuberculous infection, in acute osteomyelitis. This, however, differs from the more common condition by its rapid onset and virulent and destructive course, in marked contrast to the insidious approach of tuberculosis, sometimes covering months and months.

The germs of osteomyelitis will do in a few days what

tuberculosis as a rule will not accomplish in many months.

These four conditions, each distinct, yet resembling one another in a few general symptoms are commonly classed together as "Pott's disease."

The etiology of true tuberculous spondylitis is due to an infection of *Bacillus tuberculosis* into an area of previous inflammatory action. This theory was taught

by Phelps in this country and by Billroth on the Continent some years ago, and is now the one generally accepted the world over. That the bacilli inoculate tissue not embryonic is impossible. The result is a slow growth of tuberculous tissue. As the area of inflammation extends, inoculation takes place with destruction of bone. This was formerly known as caries, which is a term that means nothing and will eventually be dropped from the nomenclature of the subject.

The germs of tuberculosis enter the system primarily, as a rule, through the lymphatics. A child playing in the back yard of a tenement house, in an atmosphere contaminated by germ life caused by the old woman beating the carpets from an infected room, where an individual has died of tuberculosis or osteomyelitis, inhales the spores of the germ.

These spores are immediately absorbed by the lymphatics from the mucous membrane of the pharynx and the trachea and carried to the neighboring lymphatic glands. The lymphatic glands are rich with cells, and are a good soil for the reception and growth of the germs. The cells or phagocytes of the lymphatic glands are at once attacked by the germs and destroyed, until the entire gland is converted into a pus or tuberculous cavity, depending upon the kind of germ absorbed. These are the large glands seen in the necks of children and called by the older authors "strumous or scrofulous gland." Ulceration now commences in the gland, burrowing takes place in the direction of least resistance. The gland is surrounded by a vascular network of veins and arteries. When perforation of the gland takes place from ulceration, its contents may discharge directly into the vein; thus it can be readily seen how the circulation becomes contaminated with germ life from the reservoir which is constantly

discharging into it. Now, if the child playing in the back yard receives a slight injury of the spine, at once inflammatory action begins at the point of lesion already described. The blood being loaded with germs of infection carries them to the point of injury. The pathogenic germs finding a fit soil for their reception and growth attack the normal new inflammatory material and convert it into a diseased condition, with a formation of pus or a tuberculous abscess. From this point of local infection the pathogenic germs find their way into adjacent tissues, destroying them as they advance and enlarging the diseased area. Should the body of the vertebra be involved, as is the rule, in the majority of cases, its partial destruction is simply a matter of time, *unless* the destructive process is checked by appropriate treatment, the focus of disease circumscribed, and ankylosis of the affected vertebrae accomplished.

Why it is that one child may receive a blow, but will not develop the disease, while a second child also receiving an injury will develop it, is an interesting question. It depends on the relative disease-resisting power of the cell life of the individual. In the one child the

all cases of lateral curvature are to be considered as cases of lateral rotary spinal curvature. When more than one curve occurs it is then called double lateral rotary spinal curvature. One of the most common symptoms of lateral curvature is the projecting shoulder-

der-blade and the drooping shoulder. These are cases that find their way to various bandagers, who adjust worthless appliances, and the apprehensions of the mother are put at ease by such charlatans until after a year or two when the orthopedist is consulted, he finds an incurable curve in the vertebra produced by absorption. Then the projecting shoulder-blade, the drooping shoulder, the prominence of the ribs on one side of the vertebra—as the patient is bent forward—the absence of pain and spasm of the muscles, the general good health of the patient, are symptomatic of curvature.

In case of tuberculosis of the spine the surgeon should always make a diagnosis before deformity occurs. To do this in a child only a year and a half old is sometimes difficult.

In these cases, as a rule, there will be the night cries; screaming of the child when the mother lifts it; bending forward of the body elicits pain anteriorly from the point of disease; the patient placed upon its back

when lifted to an upright position with the hand under the head rises with a rigid spine; patient in the sitting position, you standing behind it, will present a rigid spine when bent from side to side; if the disease is located in the lumbar region the good old doctor has

embryonic cells resist the attack of germ life, while in the other they succumb to the invasion of disease.

Rotary lateral curvature differs from tuberculosis of the spine. It is never produced by inflammation or disease of the spinal column. The etiology of these curves occurring high in the vertebral column, either in the dorsal or cervical region, is, I believe, nearly always congenital or rachitic. A rapidly growing child who sits in a faulty attitude, or stands in such a position as to constantly curve the spine, will often develop rotary lateral curvature.

Curves that occur in the lumbar region are usually due to such a cause as this or to a shortened limb, or tilted pelvis. Paralysis of certain muscles may also be an important factor in the etiology of these deformities. I have known cases where great deformity resulted from the intercostal adhesions following the absorption of a pleuritic effusion. Deformity of this kind is seen in the dorsal vertebrae for the reason that the spine bends where there is a change in the ribs and in the muscles between the ribs.

The deformity in lateral curvature is produced by absorption of the vertebra from pressure. As the spine bends, rotation always takes place in the direction of curves. The body of the vertebrae always rotate toward the convexity of the curve. Then we say that nearly

probably treated the case for worms; if in the dorsal region, for asthma. But when the symptoms which I have enumerated are present, although there is no deformity as yet of the spine, you would be quite certain of making a diagnosis of Pott's disease.

If the spine is flexible in its continuity there is no Pott's disease; if rigid it is certain to be present.

Bone Changes.—On one side, the bodies of the vertebrae become absorbed by pressure, but on the opposite side they are normal. As Phelps has said, there is not a single straight spine in the world. If there were the person would break his head every time he jumped six

feet. Every lateral curvature, to be cured, must have compensating curves so as to allow a vertical line to fall through the center of the curves and to fall inside of the base formed by the feet. In some lateral curvatures, as in rickets, the deformity is due to pressure. Ossification, as in the ossified man, is produced by central nerve-lesions.

Treatment must be based on rational principles. I would treat lateral curvature with gymnastics and a support to relieve pressure; and Pott's disease by fixation to give nature a chance to repair.

Lateral Curvature.—Some orthopedists say every brace produces atrophy. Others that bracing is all that is required to remove pressure and prevent absorption. Bracing properly done does not produce absorption. I know of a gymnasium professor who relieved one patient and made an athlete of him. Of course, the curvature still remains. It is a very good plan to always determine the extent of bone changes before beginning treatment. Bending forward shows it. A straight line along the back demonstrates the extent of deviation. The diameter of the vertebral column is two inches. If a displacement of one-half of this occurs to either side, there is unstable equilibrium and exercise cannot correct. The patient must be braced so as to produce stable equilibrium. A child of 3 years cannot be properly braced, because the pelvis is too small as compared with the thorax, and the brace will slip. Put on a Bonnet's cuirass, or better, Phelps' plaster-of-paris portable bed which is good also in Pott's disease and hip-disease. Dr. Phelps got the idea from observing an Indian squaw carrying her baby. In spinal braces, when the band around the pelvis is narrow and small, the appliance will tilt. I believe

suspension and then fixation is necessary. This is the principle of one brace invented in 1754. The Hessing corset was invented in 1764. Many apparatuses modernized were used more than a century ago. Sayre was the first man in this country to make a suitable apparatus for Pott's disease or lateral curvatures—the plaster-of-paris corset. It is good, but to its routine use in all cases of spinal disease, of all kinds, I have objections—it is heavy, cumbersome, unclean, and it wears out and so changes have to be made; but it is the best of all braces. Then there is the substitution of other materials for plaster-of-paris, such as leather, and cow-hide which proved nonavailable, and wood, wire, celluloid and paper, none of which are of any value in these cases. A spinal support must be *absolutely unyielding*, or it is entirely useless.

If the disease is located above the third dorsal vertebrae, no corset or brace without the aid of the jury-mast can be adjusted so as to be a support, owing to the fact that the weight of the head and shoulders operate upon the point of disease or curve. In such cases the jury-mast should always be so adjusted as to transmit the weight of the head through the corset to the hips. All of the arguments which have ever been advanced against the use of the corset amount to nothing in the presence of an established fact. You will observe that a child with lateral curvature, after the corset is adjusted is $2\frac{1}{2}$ inches taller than without the corset. If anybody can explain to me what makes the child taller, outside of the support he is given by the corset, I will concede that the corset does not support. Until this question is answered I will continue to believe that the arguments advanced against the support of the corset are all fallacious.

To make proper corsets from plaster-of-Paris, suitable material must be used. H. B. Claflin & Co. make for me a special crinoline known as No. 100

hospital crinoline. It has the proper amount of sizing and material and a total absence of indigo. The plaster-of-paris I have had the White Dental Manufacturing Company, of New York, put up in 50-pound tin packages, fresh from the oven. This cloth and plaster-of-paris, when properly united, makes a perfect

plaster-bandage. Tear the crinoline into strips 6 inches wide and 6 yards in length, draw the cloth over a pile of plaster-of-Paris on a table, and with the hand rub off all excepting enough to simply fill the mesh of the cloth; roll the bandage loosely, that it may take water quickly, and it is simply perfection. A

than the steel brace, and it supports as the steel brace cannot.

When a patient is suspended in Pott's disease of the spine, and a jacket properly adjusted, he is at once relieved from a condition of pain and suffering, and to such an extent that any amount of pressure upon the shoulders does not produce pain. In rotary lateral curvature of the spine, a plaster-corset with lacings is made to fit this suspended and straightened position. After the corset has been adjusted the patient is 3 inches taller than before its application.

To make a good jacket, or corset, good materials must be used. In addition to these, as Phelps has so truthfully and forcefully stated, the whole appliance is worthless "unless the plaster is mixed with a proper amount of gray cerebral matter." In the absence of the latter it is worthless.

If the patient can afford the greater expense, I always advise the aluminum corset, for although the first cost is greater than for the plaster-of-paris support, yet before treatment is completed the metal appliance will have proven the cheaper, for it is practically indestructible. Phelps calls it "the end of the law in spinal bracing" and I believe his statement to be correct. I do not suggest the alumi-

tight-fitting shirt must now be adjusted to the patient. The shirt which we now use is a long stocking, and costs about 25 cents a yard. Mr. Ford, of Thirty-second Street and Fifth Avenue, New York, furnishes it to us. It fits perfectly. The life of an ordinary jacket made of plaster-of-paris is about 3 or 4 months. They last longer in cool weather than when the patient is freely perspiring in summer. Rapid setting of the plaster is necessary because the hand holds it to the corrected position of the deformity. This material, with the stockinet sold by

Ford, completes the materials necessary to make a perfect corset. The crinoline costs 6 cents a yard, the plaster-of-paris 3 cents a pound, and the stockinet 30 cents a yard. A corset for a child 6 years old should weigh not to exceed 1½ pounds, and for an adult 2½ pounds. This makes a support as light or lighter

num corset as a substitute for plaster-of-paris in acute Pott's disease and lateral curvature. I suggest it rather to take the place of such braces in cases requiring permanent bracing, or in individuals who are desirous of securing a support at any time which combines durability with lightness and comfort. So soon as a case of lateral curvature has been arrested, or the greatest amount of benefit has been derived from treatment, the aluminum corset will then be found a most agreeable permanent support. The aluminum corset has these qualities to recommend it to the patient:

1. Lightness.
2. Durability.
3. It is thin and does not interfere with the form and clothing.
4. Being extensively perforated makes it the coolest and most agreeable of supports.
5. The patient can wear it during bathing.

An ordinary corset weighs from one to two pounds, depending upon the size. To prevent cracking and to protect it from perspiration it is covered with a waterproof enamel, which is applied by heat.

Phelps invented the duplex hinge in this corset by

means of which the unequal planes of it can be perfectly hinged.

To make an aluminum corset, first make a plaster-mold of the body. Fill this and from the cast thus obtained an anvil of iron is made. Over the metal anvil the aluminum is hammered into shape. It takes 2 skilled workmen 2 weeks to make one of these corsets. When fitted to the body the corset is shellacked with a preparation that makes it impervious to perspiration. With an apparatus of this kind the patient can go in bathing. In Pott's disease the same kind of a corset can be used if it is put on with wire lacing and kept on. In lateral curvature cases the corset is to be taken off daily and the patient instructed in proper gymnastic exercises. In Pott's disease the spinal support is not to be removed except at the surgeon's directions.

The new operation of forcible replacement by Calot, of France, was done by Hippocrates, 500 years B.C.; was revived in the time of Ambrose Pare, in the fifteenth century, and again in this generation by Harda, of Texas. This is a procedure adaptable only for selected cases, and at the hands of experienced operators. Long ankylosed cases, or cases in which abscess with much deformity exists, should not be broken up. In the early history of some cases forcible reduction has been of much benefit, but it is an operation attended with great risk.

FRACTURE OF THE EXTREMITIES.

A Report of a Second Series of 500 Consecutive Cases, Verified by Radiographs.

By G. G. ROSS, M.D.,

of Philadelphia, Pa.,

Assistant-Surgeon to the German Hospital,

AND

M. I. WILBERT, PH.G.,

of Philadelphia, Pa.,

Director of the Radiographic Laboratory at the German Hospital.

In reporting this second series of cases of fractures of the extremities, we have in mind the value of accurately compiled statistics, as stepping-stones for the advancement of medicine along scientific lines.

It is generally conceded that the existing treatises on fractures and luxations will require a thorough revision within the next decade. The rewriting of these books should be done with extreme caution, and the material presented as facts should be based on a large and varied number of cases, the diagnosis of which have been verified by means of the Röntgen-rays. We fully realize that the statistics presented here, while they are based on the practice in a large general hospital, are still apt to be somewhat influenced by more or less local conditions, such as the class of industrial plants from which a large proportion of the accidents would naturally be derived, and for this reason we should like to induce other operators to collect their data in a methodic and scientific way, with the ultimate object of contributing such observations to the better understanding of this class of injuries.

Our methods of procedure were quite fully defined in a paper reporting the first series of "Fractures of the Extremities" and published in the PHILADELPHIA

MONTHLY MEDICAL JOURNAL for June, 1899. In addition to what we have said there we should like to say a few words about the use of the fluoroscope. This instrument, while of great interest and of undoubted utility in the examination of the various organs of the body, is of little or no use in the routine practice of discovering fractures. In our estimation the fluoroscope will not give more or better information than will a careful clinical examination, and to do this it usually requires the placing of the part to be examined in an awkward position, and its being held there, or even rotated, causing the patient an unnecessary amount of pain and inconvenience. Then, again, the operation, to be conducted satisfactorily, must be done in a dark room so as to allow the observer to have his eyes properly adjusted to the comparatively small amount of light usually furnished by the fluorescent screen. If we bear in mind that a very large proportion of our patients are liable to be somewhat nervous and excited, after meeting with an accident, we will readily appreciate why so many become restive when placed in a dark room with a buzzing, spluttering induction coil, that not only sounds uncanny and looks weird, but in a short time imparts to the atmosphere, in a confined space, the odor of a good old-time sulfur-match.

In the photographic plate, on the other hand, we have a means of showing all the details of a fracture, and when properly interpreted we are in a position to say exactly the direction and extent of the lesion, and in addition to this, we have a complete and correct record of the injury for future reference. By taking two pictures, at right angles to each other, it is practically impossible for a fracture, even the slightest *in-fracture*, to escape us, taking for granted of course that our technic is not at fault.

The practice of taking all fractures at two separate angles is one that should be followed regularly, as it is possible to have a fracture of such a nature that in one direction it would show little or no deformity, while a view in an opposite direction will show extensive injury or a marked deformity. Attention has been called to this fact repeatedly. Among the first was a contribution from the Radiographic Laboratory of the German Hospital, reported by Dr. J. B. Deaver, before the Academy of Surgery of Philadelphia, December 2, 1897, and again in the paper reporting the first series of fractures, as quoted above. Another great advantage of the photographic plate is the fact that the examination may be conducted in a well-lighted room and consequently there is little or no necessity of exciting the patient. In addition to this the part to be examined may be placed in a comfortable position for the patient, and in this way the examination can be made with a minimum of pain or discomfort, and a maximum of information, a matter of satisfaction to the physician who is to treat the injury.

Much has been said and written for and against the accuracy and value of the information obtained by means of the Röntgen-rays. We may be pardoned therefore for offering the following opinions.

When making use of the x-rays, as in making a radiograph, we employ a purely mechanical process that, when properly carried out, must give us mathematically correct results. The one important point to remember, in this connection, is that a radiograph is a fixed shadow, the result of interference in a cone of light or energy emanating from a fixed point. This shadow, therefore, depends on the relative positions of

the source of energy, the body casting the shadow, and the screen or photographic plate on which the shadow is cast. It is obvious, then, that unless we are in possession of all the facts and factors that have entered into the making of any particular radiograph, we cannot conceive of an absolutely correct impression of what it actually represents.

FIG. 1.—An outline drawing of femur from plate No. 2247, shows position of small fragment and longitudinal crack.

FIG. 2.—Outline drawing from No. 2155, shows fracture through outer portion of head of tibia. Patella not shown.

The possible deception and abuse that might arise from the indiscriminate use of radiographs as evidence in a court of law has prejudiced many surgeons and medical practitioners against the routine use of the x-rays as an aid in the diagnosis and treatment of fractures. There seems to be little or no difference of opinion as to the scientific value of these rays as an aid to the surgeon. But there is considerable doubt as to the advisability of admitting radiographs as evidence in a trial at court, especially at the present time. For while the x-rays have been known and used for upward of 5 years, their use has necessarily been restricted by various causes; among these being the cost of suitable apparatus and the requisite knowledge and technical skill that is necessary to operate the apparatus after it is installed. It might be safely said that out-

FIG. 3.—Outline drawing from Case No. 3169 shows extensive fracture of inner portion of head of tibia; patella not shown.

side of the work done in the radiographic laboratories connected with the larger hospitals comparatively few operators have had the necessary experience to make a satisfactory interpretation of a radiograph, and until it has been found feasible to properly standardize the making, and consequently the interpretation of a radiograph the medical profession should not urge or advise the admission of the x-ray picture as evidence *per se* in a court of law. In the present series of cases we have included some additional data that we trust may be of interest especially to the statistician, or the author of a textbook on this subject. Of the 500 cases

reported here 304, or nearly 61%, were fractures of the upper, while 196 were fractures of some portion of the lower extremity.

There were 53 fractures of the hand. Of these one or more of the phalanges were involved in 12, and the metacarpal bones in 41 of the cases.

Of the 114 fractures about the wrist joint, 28 involved the radius and the styloid process of the ulna, and in 4 the injury to the radius was accompanied by a fracture of the ulna higher up, or distinctly above the articulating surface of this bone.

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 4.—Diagram to illustrate location and frequency of fractures of the extremities.

The radius alone was found fractured in 38 cases, one being multiple; 8 of the cases had a fracture of the ulna alone, and 36 included one or more of the carpal bones; in 4 of these latter cases the carpal fracture was accompanied by a fracture of the radius, in 3 by a fracture of the ulna, and in 1 by a fracture of both radius and ulna.

Fractures of the carpal bones, when not accompanied by extensive laceration of the soft parts, are very apt to be overlooked, and although the figures given here may seem excessive we ourselves feel that they represent a fair average of the cases that would ordinarily be encountered. In this connection we would like to call attention to a paper on this subject published in the PHILADELPHIA MEDICAL JOURNAL for October 13.

The bones of the forearm were involved in 26 of the cases, of these 12 were fractures of both bones, while in 9 the radius, and in 5 the ulna alone were found broken.

Of the 65 fractures into or near the elbow joint, 5 were of the olecranon, and 7 of the coronoid process, and 2 included both the olecranon and the coronoid processes; one was a fracture of the coronoid with involvement of the head of the radius, while another had a fracture of the coronoid with an extensive injury to the lower end of the humerus.

Fractures of the coronoid are somewhat difficult to recognize from clinical data alone, and formerly they were thought extremely rare; in this series we have a total of 12 cases, making an average of 2.4% of the fractures—a rather high percentage for what was supposed to be a rare fracture.

The head of the radius was found fractured in 5 cases, while the same injury accompanied by a fracture of the outer condyle was found in 2 more. The condyles of the humerus were found injured in 41 cases, as follows: 9 of the inner, 16 of the outer, and 15 of both, and in one case a longitudinal fracture into the lower end of the humerus was found.

rather out of the average, and also as illustrating the value of Röntgen-ray information. L. K., a sailor, 19 years of age, was injured one week prior to admission to the hospital, by falling from a yardarm of a ship while at sea. When admitted to the hospital it was found that he had sustained a fracture of the right femur; he was referred to the radiographic laboratory to find the exact condition of the fragments. This is well illustrated in the tracing. The loose fragment of bone had become displaced in a transverse position to the shaft, and, in addition to this, it was found to be cracked longitudinally. Operation was thought advisable; the patient was etherized and the loose fragments of bone removed; the ends of the bone were then brought in apposition and fixed by silver-wire sutures. Recovery was uneventful, with perfect union.

Of the 18 fractures at or about the knee, 5 involved the patella, 4 the femur, 2 both the tibia and fibula, and 7 the tibia alone. Several of these latter cases were quite interesting, and as they seem to be of a rather unusual type we have decided to describe them more fully. Fig. 2 is from the knee of Mr. J., 44 years of age, who was pushed or fell from a moving trolley car. He landed on his feet, but on attempting to walk his left

TABLE OF SEX AND AGE OF PATIENTS, AND OF SIDE INVOLVED.

The shaft of the humerus was found broken in 10 cases, while the same bone at or near the head was found fractured in 8 of the 36 injuries about the shoulder joint. In addition to the 8 mentioned above, the humerus was involved in 2 cases of fracture of the acromion. There were 13 fractures of the clavicle, 4 of these were accompanied by more or less extensive injury to the acromion. The scapula alone was broken in 13 cases, 3 of these fractures were confined to the acromion, and 2 to the coracoid process.

The above figures would seem to indicate that a so-called sprain of the shoulder, like the corresponding injury at the elbow or wrist, is liable to be a more or less extensive fracture, as a result of unrecognized and untreated fracture at or near the shoulder joint, as at other joints we are liable to have excessive callous formation which interferes with the function or free use of the joint, and causes persistent pain; this condition is liable to be mistaken for chronic rheumatism.

The hip and thigh were involved in 15 cases, of these 8 were fractures of the shaft of the femur, while the upper portion of the bone including the neck was found broken in 7 cases.

Fig. 1 illustrates a case that is interesting in being

leg gave way under him and he found that he was unable to place any weight on it. There was evidently some severe injury about the knee-joint. The radiograph made after his admission to the hospital showed a longitudinal fracture of the head of the tibia completely separating the outer portion of that bone. This is well shown in the diagram, which is an outline drawing from the original radiograph.

A somewhat similar case, but involving the opposite side of the head of the tibia, is illustrated in Fig. 3. This is from a radiograph of the right knee of ———, who was thrown from a bicycle and sustained a fracture of the inner portion of the head of the tibia. In two other cases there was a fracture of the upper and outer edge of the tibia, accompanying a luxation of the head of the fibula and probably caused by the tearing away of one or more of the ligaments connecting these two bones.

The leg was found broken in 34 cases. Of these both bones were fractured in 24, the tibia in 4, and the fibula alone in 6 of the cases. Here, as in the case of the other long bones, the tendency of the line of fracture, especially when at or near the middle of a shaft, seems to be rather more transverse than oblique.

There were 76 fractures at or about the ankle. Of these 17 involved the inner, and 23 the outer malleolus, while 17 included both malleoli; one or more tarsal bones were involved in 19 cases, 1 of these was accompanied by a fracture of the fibula, and 3 by fractures of the tibia.

The foot was injured in 33 cases, including 25 fractures of the metatarsal bones, 5 of the tarsal and metatarsal, 1 of the metatarsal bones and phalanges, and 22 of the phalanges alone.

A survey of the accompanying table may be of interest. Of the cases enumerated here, 434 were males and only 66 females. This is probably not a correct ratio of the total number of injuries sustained by the sexes, as it is generally supposed that women are not so likely to seek hospital treatment as men, and if this be so the proportionate number of women would, of course, be greater. In many cases this apparent difference is readily explained; for instance, fractures of the hand were, according to our figures, 25 times, and fractures of the foot 50 times more frequent in men than in women, and when we consider that these fracture are most liable to occur to persons engaged in working about the moving parts of machinery, or in handling heavy weights, we can easily see why men are more likely to sustain such injuries than women.

The two sides of the body are remarkably evenly represented in this series of cases, 271 of the fractures occurring on the right, and 229 on the left side.

The age columns are also of interest. Of the 47 fractures occurring between 1 to 10 the greatest number, 19, were fractures of the elbow, with fractures of the arm and the leg of equal frequency. From 11 to 20 there were 103, and from 21 to 30 there were 119 cases. In both of these columns fractures of the wrist predominate, while among the patients ranging in age from 31 to 40 the predominating fracture was one of the ankle, with fracture of the wrist second in frequency; on the other hand, fracture of the wrist comes into prominence again among the 73 cases from 41 to 50, as well as in the 17 cases from 61 to 70.

Of the 4 cases above 70 years of age, one was a man who said he was 83 years of age, a stonecutter by trade and still regularly at work. While at work on a large stone, or in attempting to move it, the stone slipped and struck him over the metatarsal bones, and, as was subsequently shown, fracturing the 2, 3, and 4, metatarsals about the middle. Fractures of the hand seem to be distinctly more frequent between the ages of 11 to 50, while those of the wrist seem to extend to 70; the reason for this would appear to be that fractures of the hand, as a rule, are the results of blows or crushes, while fractures of the wrist usually follow or occur as a result of a fall on the hand or wrist.

Fractures about the elbow were most frequent in the first decade, and appear to decrease progressively for each successive period. Fractures of the foot, as would be expected, are most common between the ages of 21 to 50, or during the years when men would most likely be employed in the hauling or handling of heavy weights.

Fractures of the ankle, like the corresponding injury about the wrist, are divided over a longer period of time, occurring in slightly varying proportions from 11 to 70 years of age. The additional diagram of the arm and leg is added to facilitate reference, and comparison as to the frequency of fractures.

SUMMARY OF FRACTURES REPORTED IN THIS SERIES.

Upper Extremity.		Lower Extremity.	
Hand	53	Thigh and hip	15
Phalanges	12	Shaft of femur	8
Metacarpals	41	Head and neck	7

OVARIAN CYSTS IN COLORED WOMEN, WITH NOTES
ON THE RELATIVE FREQUENCY OF FIBROMAS.
IN BOTH RACES.

BY DANIEL H. WILLIAMS, M.D.,

of Chicago, Ills.

Attending Surgeon to the Cook County and Provident Hospitals.

IT HAS been held by surgeons and gynecologists since the time of MacDowell, and until a very recent period, that colored women did not develop cystic tumors of the ovaries. This "impression" has been reiterated and handed down from one generation to another without any attempt, until recently, at scientific investigation and report. Men of large experience in the fields of surgery and gynecology, teaching in the best schools of the country, repeated this statement from year to year to their classes, that colored women "did not have ovarian cysts."

Brown,¹ in his carefully prepared paper, says: "One frequently hears surgeons say: 'The tumor before us presents all the features of an ovarian cyst, but inasmuch as the patient is a negress, it is certainly not so, but a tumor of different origin (cystic myoma, etc.), as multilocular cysts are unknown in the negress.'" E. Tipton² also states that he has never seen an ovarian tumor in a pure negress.

This "impression" would undoubtedly have gone on unchecked had not methods of study and diagnosis changed. He is an indifferent surgeon who would today extirpate a tumor and base his diagnosis on the naked-eye appearance of the specimen. An opinion expressed on a pathologic specimen by a distinguished operator, 50 years ago, was never called in question. It is not so today, for the opinion of the most learned operator in the world would not be accepted until the-

specimen had been worked through a pathologic laboratory, and a written report submitted on it. It is the difference between the old and the new methods of studying cases; on the one hand, an opinion is founded upon a laboratory report; on the other, the diagnosis is guessed at from the naked-eye appearance of the specimen in the operating room. Comparatively few operators have the necessary laboratory facilities for studying their own cases in all of their bearings. The number of those who have taken up the study of ovarian cysts in colored women is very few. They have shown us, however, that colored women do have ovarian cysts of every variety. Not only the fair-skinned woman, but the woman of the blackest skin furnishes many excellent specimens of multilocular adenocystoma that she was thought not to develop.

After it was found that colored women did develop ovarian tumors, it was still held by some that the tumors were found only in fair-skinned women, and as C. H. Mastin said, in discussing Stone's paper: "Possibly the Alabama negro has not evolved to the cyst-bearing age, and, as yet, is not enjoying the full benefit of their white cousins in this pathologic particular."

In the collection of cases I will submit, it will be shown that the majority of these are in women of black skin, and three of them hail from Alabama.

Dr. I. S. Stone wrote a circular letter to the members of the Southern Surgical and Gynecological Association, inquiring "if they had operated for multilocular ovarian cysts in colored women, and, if so, to state the exact color of the patient." This proves that the theory that colored women do not have ovarian cysts of any variety, has been of necessity abandoned. The collection of cases submitted in this paper, of multilocular adenocystomata in black women ought to, and I think will, satisfy the keenest searcher after truth, that the dark-skinned negro women "have evolved to the cyst-bearing age."

The literature on this subject is very meager. Few articles can be found in the Index Catalog of the library of the Surgeon-General's office at Washington.

Dr. Thomas R. Brown's article is valuable from the fact that the cases he reports have been worked through the Pathological Laboratory at the Johns Hopkins Hospital, and are microscopically differentiated. Specimens with but one cavity are not called unilocular, because they appear to have but one cavity. In the table which is given here, Dr. Brown recorded the cases from January 31, 1892, to January 31, 1898.

OVARIAN CYSTS IN THE NEGRESS.

By THOMAS R. BROWN, from January 31, 1892, until January 31, 1898.

VARIETY OF CYSTS.

Total number of cases of all kinds treated in the gynecological service.		Dermoid cysts.		Simple cysts (Graafian follicle and corpus luteum cysts).		Unilocular and Multilocular cysts.		Papillary cysts.		Parovarian cysts.		Intraligamentary cysts.	
		W.	C.	W.	C.	W.	C.	W.	C.	W.	C.		
3996	589	17	7	88	3	53	2	14	0	4	0	3	0

Of the 4,585 women who entered the service for treatment, 3,996 were white and 589 colored. This

table shows that of unilocular and multilocular cysts, of the 55 cases only 2 were in colored women, *i. e.*, a proportion of 1 in 26.5. Dr. Brown says: "This is of special importance, because this form of cyst of the ovary grows to the largest size, and it is this variety of cyst which many surgeons declare never occurs in the negress." He says further: "It will be seen that with the exception of dermoid cysts, ovarian cysts are really much less common in the colored race, the result being more or less indefinite, due to the fact that the diagnosis was made clinically and macroscopically, and not microscopically."

In another table Dr. Brown analyzes 244 ovarian and parovarian cysts, operated upon in the hospital from the latter part of 1893 to October, 1898. These cases were analyzed microscopically and diagnosed in the gynecologic pathologic laboratory. I mention only his unilocular and multilocular cysts. He gives 94 cases, 88 in white and 6 in colored women, *i. e.*, 1 in 14.7, or more than twice as common among white women. Of these 6 cases in black women, 1 was unilocular, 4 multilocular, and 1 undecided. He concludes by saying: "The possibility of their being present should always be considered, when the physical examination points in that direction."

When a laboratory examination determines that over 75% of the so-called unilocular ovarian cysts are multilocular, Kelly⁴ shows clearly the fallacy of operating-room diagnosis by presenting two tables, showing the marked contrast between operating-room and laboratory diagnosis—36 cases unilocular and 38 cases multilocular ovarian cysts, differentiated macroscopically in the operating room. In another table of 60 cases, he presents 57 cases multilocular cysts, and 3 unilocular cysts, examined in the pathologic laboratory. Showing the contrast of the two methods of diagnosis, he adds the group of unilocular cysts in the ovary; after having been more carefully examined these tumors were reclassified and put with the multilocular cysts. Such a reclassification was also made necessary by the frequent discovery of trabeculae on the inner cyst-wall. These were clearly the remains of partitions between originally separate cysts, which later became fused by pressure and atrophy of the septa, or by spontaneous rupture from tension."

Stone's³ paper is valuable from the fact that it will stimulate observation and encourage study in a quarter where the colored population is largest. The answers sent in by the most distinguished surgeons and gynecologists in the South, on this interesting as well as important subject, do not tell us that these growths had been studied outside the operating room. The large number of unilocular cysts reported make it possible, in the light of Kelly's analysis, that a sifting of these cases would have gone far toward fixing the frequency of multilocular cysts in colored women. That ovarian tumors in colored women are not rare has been shown already by Dr. Brown's paper, and this fact was made still more clear by Kelly's table already given in this paper, in which microscopic examination shows that over 75% of unilocular tumors are really multilocular.

A point referred to by the few writers and observers is the comparative infrequency of these tumors in negroes, assuming that this refers to a person of dark skin. It is stated by the Census Bureau that it is thought that the number of negroes in this country will reach 12,000,000; of this number it is said not one-fourth are full-blooded. It is a well-known fact

that in the same family are often found brothers and sisters—black, mulatto, and white—born of the same parents. The color of the skin in this country furnishes no correct index of the purity of the blood of a colored person any more than it does the purity of the blood of a white person; therefore it may be pertinent to inquire if this interesting question is to be confined to negroes of black skins, brown skins, olive skins, or to any shade of color in the negro. Who is to determine where the line is to be drawn? For a further study of the relative shades of color of the native African, I refer you to a colored plate in Meyer's *Konversations-Lexicon*, published in Leipzig, giving types of all the principal tribes of Africa. This plate shows complexions varying from a clear mulatto to those of ebony black.

That a greater interest has been taken in the surgical diseases of the negro is evident from the classical paper of Dr. Rudolph Matas. Before the war, and for years afterwards, little attention, if any, was paid to the surgical diseases of the negro. Very few had been operated upon, and very small was the number of hospitals in the South for either white or colored people. Now all this has changed to a great extent, and surgery in the negro is no longer neglected, since we find hospitals for colored people all over the North, and in the South as well. Trained physicians and surgeons of the race have taken up this work among the colored people, and the work of investigation and study of diseases in the colored race, inaugurated by the white profession, is continued by the colored scientists. The reason so few ovarian tumors have been found in negro women is manifold. First, I would mention the presence of inborn superstition in colored people. The ignorant and uneducated colored people have an abiding faith in liniments, ointments, plasters, and a long list of most repulsive panaceas. Second, they have a natural dislike and horror of hospitals; they shun the hospital. Of this I was convinced while in charge of a large hospital devoted almost entirely to the care of colored patients. A great many of those who entered were moribund, incurable, or past the operative stage of their diseases; others were kept away on account of poverty or inability to get to a hospital. But the hospital is losing its terrors for colored women, and they begin to flock to these places where their cases will meet with proper treatment and a correct diagnosis. How often do we find faulty diagnosis where colored people have presented themselves for examination? It often happened that their cases were diagnosed as "dropsy" and treated as such. Dr. D. S. Lamb, in the paper in which he records 183 autopsies made on colored women, refers to such cases.

The fear of the ailment being suspected to be pregnancy also prevents many ignorant women from presenting themselves to be examined, a fact which has come under my own observation. A ruptured cyst, a twisted pedicle, or a hemorrhage would cause death, and only by an autopsy would we be acquainted with the real cause.

The statements and tables of Dr. Rudolph Matas, and Dr. D. S. Lamb, and Dr. Brown, are interesting and convincing, on the relative frequency of ovarian cysts in colored women. They show that these cases exist in nearly equal numbers in New Orleans, and are almost as frequently found in Chicago and Washington, and that these cases had been studied and reported 35 years ago, by Dr. W. C. Miner, of Alexandria, Va.

Table given by Dr. Rudolph Matas, of New Orleans, in a communication to Dr. Stone (Washington, D. C.), November 27, 1897, taken from the Charity Hospital Reports.

	White.	Colored.

Total cysts	6	11
Total cysts	52	45

The population of the Charity Hospital during the 10 years, 1886-1896, was 45,563 whites and 23,409 colored. Total 68,972.

The question of the frequency or the possibility of ovarian tumors in colored women, came up during an operation on a woman in Washington, referred to in the paper of Dr. Stone. Dr. Lamb kindly looked through the Museum of the U. S. Army shortly afterwards with me, and we had no trouble in locating several fine specimens of ovarian tumors, mentioned in his report. Dr. Matas' statement and tables are so important that they are given in full. He says: "When a student, I saw at least two ovarian cysts in colored women. In reports of 'Charity Hospital,' 1896, I find 2 simple and 1 multilocular cyst in colored women, all presumably operated upon. I have not looked up older reports, but am satisfied that it is the general impression here that the ovarian tumors are not considered very rare in the colored race."

Dr. Michinard says: "I remember having removed at least 10 ovarian cysts when I had charge of the colored section of the gynecological department of the Charity Hospital. I saw 5 or 6 more requiring surgical treatment." Continuing, he says: "I do not remember the purity of the race of the colored women in whom the cysts were, nor do I recollect how many of the cysts were multilocular. I am satisfied that the colored woman is as subject to cystic degeneration of the ovaries as the white."

Dr. Fortier, of the Charity Hospital of New Orleans, says: "From September, 1894, to November, 1896, there were 8 cases of ovarian cysts in colored women admitted into the Charity Hospital. Four was operated upon successfully; one was a double cyst; the others were not operated upon."

Dr. H. R. Black⁶ also operated upon a perfectly black woman, aged 23, March 11, 1892, for ovarian cyst. The cystic tumor was about the size of a pregnant uterus at 7 months. Patient recovered.

Dr. H. A. Royster,⁷ in his article, "Ovarian Cysts in the Negro," has this to say: "The occurrence of ovarian cysts in negro women is sufficiently rare to at least justify reports of cases as they are seen from time to time. Many surgeons of large experience in operations on colored people have never met with these tumors.

As compared to uterine fibroids in the same race they are exceedingly uncommon, and are likely to be slighted in the diagnosis of doubtful abdominal enlargements. Dr. George Ben Johnson, who was reported by Dr. Stone as not having seen a case of this kind, has sent to Dr. Royster the histories of 4 cases since operated on successfully by him, 1 being a multilocular cyst in a mulatto woman.*

Dr. Royster himself, during a practice of 4 years, mentions 3 ovarian cysts in the colored women which came under his observation. The first case was that of a black woman with a large multilocular cyst, the second a mulatto, who refused surgical interference. Diagnosis: Very large cystic tumor, but could not be confirmed. The last case was a unilocular cyst in a black woman. Operations were successful, and both patients recovered.

At the last meeting of the Mississippi Valley Medical Association, Dr. A. H. Cordier,⁸ of Kansas City, Mo., mentioned the case of a woman, colored, 43 years of age, who had carried an ovarian cyst for 11 years. The cyst, with its contents, weighed 160 pounds. The patient died on the ninth day following operation, from exhaustion.

Dr. William T. Briggs,⁹ of Nashville, Tenn., discussing the paper read by Dr. Tiffany, "Comparison Between the Surgical Diseases of the White and Colored Races," stated that he had one case of regular ovarian tumor in a negro, weighing 100 pounds. It was probably the second case he had seen in the negro.

Dr. Davis W. Yandell,¹⁰ of Louisville, Ky., has seen but two ovarian tumors in the black race. (*Ibid.*, p. 271.)

I give here a table showing all the cases as I found them. Another general table tells if they were unilocular or multilocular cysts.

I. OVARIAN CYSTS IN COLORED WOMEN.

Cases reported and collected by:

Dr. R. Matas	45	Dr. W. I. Briggs.....	1
Dr. T. R. Brown.....	32	Dr. D. W. Yandell.....	2

Total, 64.

In my first year of practice I had a woman with a large abdomen present herself for diagnosis. She was operated on at the Woman's Hospital and found to have multilocular cyst. Within 6 months I saw another and referred her to Dr. Henry T. Byford. From 1886 to 1893 I had 11 cases that I operated upon

for unilocular or multilocular cyst. From 1893 to 1898 I saw 6 cases in the morgue at Washington and 5 in wards, which were diagnosed as ovarian cysts, but who refused operation, and 3 who were operated upon. Since my return from Washington I have had a number of unilocular and multilocular ovarian tumors—14 in white and 6 in colored women. Of the 6 colored women operated on within the past 2½ years, in Chicago, 3 were from the South. Of the uni- or multilocular cysts referred to in this paper, only 9 were found in light-skinned women. I have intentionally omitted to refer to a list of ovarian tumors of other varieties operated on during the last 14 years, for the very reason that it is no longer a question as to their relative frequency in colored women of any shade of color. During the early period of the appearance of colored women in hospitals as patients, the mortality in ovariectomy was appallingly high, and while there were many skilled ovariectomists doing excellent operative work, their results were bad on account of the almost certainty of septic infection. On account of this high mortality many white women would carry their tumors, have them tapped, and worry along until death, hastened often by some intercurrent trouble, would relieve them of their burden. This being a fact, it is no wonder that the poor colored woman, unable to receive the advantages of proper diagnosis and treatment, died without operation. There was no place where she could present her case for a full hearing, and little or no attention was ever paid to her condition. Doubtless hundreds of them have had their cysts and died a natural death rather than an operative one.

In keeping with the impression which prevailed everywhere in the profession concerning the infrequency of ovarian cystomas in colored women, and which inspired this article, is another deep-rooted "impression," that uterine fibromas were very much more frequently found in colored than in white women. I listened to this teaching while in school; I have heard it from every teacher, and met with the same statement in every textbook. In fact, it is so generally accepted that one may not be prepared to read any statements leading to the contrary. My most extensive experience has been in this line of gynecologic work, and for a number of years I worked in the Freedmen's Hospital, entirely on colored women. This period was followed by a similar one among the white and colored people of Chicago. Had it not been for an equal service in both races, I would have accepted the opinion of the profession as a whole, with a few notable exceptions, and agreed that colored women had about 4 times as many fibroid tumors as white women. I was ready to bow to this conclusion until I began to compare the number in both races. I have operated in 16 years, 357 times on both races for uterine fibromas and have found about 2% more fibrous tumors in colored women than in white. Should I complete 500 operations for uterine fibromas, I will be able to prepare some tables and statistics which may serve to indicate the relative frequency of these tumors in each race, and may perhaps correct the false "impression" which is met with everywhere. I find myself in as good a geographic position, perhaps, to study and investigate this important and interesting matter, as any one in this country, save perhaps, those on the border line between the North and the South. I agree perfectly, with Dr. Kelly, on the position he takes, and the statements he makes in regard to the relative frequency of these fibroid

* Stone finds only 15 cases outside of New Orleans, where a dark-skinned woman was operated upon for ovarian tumors, multilocular or unilocular. In Dr. Lamb's cases, the predominance of involvement of the right ovary is striking.

tumors in both races. His position geographically, is one of the best for studying any surgical conditions affecting both races. The facilities afforded him for observing, studying, and recording the conditions referred to, will cause his statistics and statements to go a long way toward establishing correct views on this subject. To illustrate this, I quote him verbatim: "From the standpoint of the relative frequency of myoma in the white and colored race, this analysis of 50 cases, while small in number, yet serves to bear out the statement made by me some months ago before the South Carolina Medical Society, that myomas were as frequent in white as black women. A number of those present at that meeting took exception to this remark, claiming that white women were able, being better situated financially, to come greater distances for treatment, than were the impoverished colored women, who, per force of circumstances, must remain at home. But according to this table (*i. e.* the table presented by Kelly) the proportion is as 6½ to 1, there being 43 whites to 7 blacks. Of the latter, 6 appeared to be of pure African descent, the seventh was a mulatto.

While the criticism offered by these gentlemen bears a certain weight, yet from the very fact that we are in the center of a large negro-population in Maryland and the adjacent States of Virginia and Delaware, the proportion should be very different from this which I present, if the statement that myomas are more frequent in the colored than in the white race, is to be sustained.

ON THE USE OF FORMALIN IN THE DISSECTING ROOM.

By WILLIAM KEILLER, F.R.C.S. Ed.,

of Galveston, Tex.

Professor of Anatomy, Medical Department University of Texas.

THE problem of preserving the human body for dissection is an exceedingly important one, and on its successful solution depends to a great extent the comfort and thoroughness of anatomic teaching. More especially is it important here in the South, where a combination of heat and moisture through 9 months of the year furnishes the best possible conditions for decomposition and the growth of molds. After many experiments I have succeeded in preserving bodies throughout the summer for dissection during the college session. They keep perfectly on the tables in all weather, at all temperatures, and for indefinite periods. They are free from odor, and pleasant to handle. It is true that they are harder and stiffer than normal, but I scarcely consider that a disadvantage. The muscles retain their prismatic form instead of stretching out into flabby

shapelessness; the viscera are perfect demonstrations of the truth of His's models. The liver, kidneys, spleen, pancreas, heart, and even the lungs, are firm and perfect in form, and the abdomen presents every organ in as true relation as is found on the operating table. The brain is hardened in situ and its form is perfect. It is also elastic and maintains its form after removal from the body, while dissections of the white fibers made by tearing give wonderful ocular demonstrations of their course, as in the corona radiata, peduncle of the cerebellum, anterior commissure and cingulum. I have tried chlorid of zinc, arsenious acid, and perchlorid of mercury, and given them all up. Of these the last gave me the best results, and I described fully my method of using it in an article, on the Teaching of Anatomy, in the *New York Medical Journal* of September 8, 1894. Cold storage I have no personal experience of, but I believe it far inferior to my method of embalming. I do not consider it a matter of any moment to preserve the red

FIG. 1.
Tongs to suspend body.

FIG. 2.

T tube for injection.

FIG. 3.

Apparatus.

color of the muscles, but the method about to be described causes less alteration in color than any other method with which I am conversant.

General Directions.—It is important, especially in warm weather, to preserve the cadaver as soon after death as possible, certainly within 48 hours, unless the mortuary be artificially cooled; but a subject need not be despaired of because it is beginning to turn greenish over the abdomen, occasionally it may be successfully preserved even then.

The necessary apparatus is a set of T-tubes the size represented in Fig. 1. These may be of glass or brass, the brass tube being preferable. The ends *a* and *b* should be the proper size to fit the average common carotid artery, the length from *a* to *b* not more than ¾ inch, so that the tube may be slipped into the shortest possible slit in the artery. A galvanized iron pail holding 5 gallons, with handle, swivel, and stopcock, as in Fig. 2; 15 feet of rubber tubing with a stopcock 1 foot from its lower extremity, and a strong pair of tongs, like ice tongs (Fig. 3), to suspend the body by the ears during part of the process, with the necessary rope and

pulleys to suspend the injecting fluid and body from the ceiling complete the equipment.

After trying the common femoral artery and intrapericardial aorta, I fixed on the right common carotid as the most suitable artery for our purpose. It is easily reached by a dissecting-room attendant of average intelligence. A very small portion of the body is disturbed and made unfit for dissection, and that is sufficiently compensated for by the preservation of the other side; by it the whole arterial system and especially the brain is readily injected; the heart and its relations are not disturbed as in aortic injections, and the internal jugular vein can be readily used for washing the blood out of the body if it be so desired. Expose the vessel in the usual way just where it is crossed by the omohyoid; clear an inch of the artery, pass two ligatures beneath it, cut a vertical slit $\frac{3}{4}$ inch long in the vessel, introduce one end of the short piece of the T-tube into the artery and then the other, and tie both in securely. Having the fluid ready, empty the air out of your rubber tubing, connect with the body and introduce five gallons of the fluid (Formula 1) into the subject while it lies horizontally under a pressure of 9 to 10 feet. The whole body should swell up and the skin become tense, with the possible exception of the legs below the knees.

After the full measure of 5 gallons has been injected the body is to be suspended by the tongs in the external auditory canal, for 12 to 24 hours, till the feet are swollen and edematous, and then it may be taken down and either put in a tank where it is immersed in a formalin mixture (Formula 2), or wrapped in a waterproof sheet and laid on a shelf till required for dissection.

Occasionally I find it desirable to use more than 5 gallons, following up the first injection with another 5 gallons in 24 hours, or at least with as much more fluid as the body will hold. This second injection is usually given with the body suspended, as the legs are the regions most difficult to reach.

In the following formulae I use the term formalin as the equivalent of 40% formaldehyd in water:

Formula 1.—For preservative arterial injection:

R.—Formalin $2\frac{1}{2}\%$ or.....	1 pint.
Carbolic acid (crystals) $2\frac{1}{2}\%$ or.....	1 pint.
Glycerin 10% or.....	4 pints.
Water up to.....	5 gallons.

Formula 2.—For tank to hold preserved bodies till required for dissection:

R.—Formalin.....	1.
Carbolic acid.....	1.
Glycerin.....	$2\frac{1}{2}$.
Sodium chlorid.....	1.
Water to make.....	100.

The brain, after removal from the body, is best preserved in a fluid of the composition of Formula 1, but if quite firm may be preserved in Formula 2.

In the above formulae the carbolic acid is used because I find that formalin in $2\frac{1}{2}\%$ solution is a very inefficient preservative against molds, while carbolic acid is strongly antagonistic to them. It is impossible to use stronger solutions of formalin than $2\frac{1}{2}\%$, as the tissues would be hardened too much for dissection. The glycerin is added to prevent the parts drying too rapidly in the dissecting-room, and also to lessen the hardening effect of the formalin. In dry climates, such as that of Denver, I should recommend higher percentages of glycerin, even as much as 20%

For the injection of the arteries with a solid mass to facilitate their dissection, I use the following formula:

Formula 3.—Arterial injection mass:

R.—A. Potassium bichromate.....	3 ounces.
Water.....	1 pint.
B. Lead acetate (commercial).....	$6\frac{3}{4}$ ounces.
Water.....	1 pint.
C. Gelatin.....	$4\frac{1}{2}$ ounces.
Water.....	1 pint.

Dissolve A, B, and C in separate vessels and keep them all at a temperature just a little below the boiling point by immersion of the vessels in a large pot of water. Strain the gelatin solution through a fine wire strainer into a vessel capable of holding 2 quarts; add to this the bichromate solution; heat *almost* (not quite) to boiling point and add gradually the acetate of lead solution, stirring all the time. A rich orange or yellow fluid (according to the temperature) will be formed (chromate of lead). Allow the mixture to cool till you can just bear the heat with your hand (110° or thereabout), and inject into the arteries with a brass anatomic syringe, using considerable force. The colored injection should not be used in less than a week after the preservative injection.

This is an excellent arterial injection for formalin bodies. Even the finest arterial twigs will frequently be found beautifully demonstrated, and the formalin combines with the gelatin to make an insoluble, elastic substance. The yellow shows up very distinctly, and the chemical union of the fluids in the gelatin medium gives very perfect division and distribution of the coloring agent. A reddish mass can be similarly formed with bichromate of potash and sulfate of copper, but I have not tried it.

For bodies that are to be used for operative surgery, $2\frac{1}{2}\%$ formalin causes too much hardening, so that it is difficult to reach the arteries through short incisions, and excisions of joints are impossible. Therefore, in preserving bodies for the operative surgery class I use only 1% formalin, the proportion of carbolic acid and glycerin remaining the same as in Formula 1.

One of the best operative surgery bodies I ever prepared was preserved by first washing all the blood that I could get out of the body with a large quantity of 1% formalin, 1% carbolic acid, and 1% common salt; the internal jugular vein being opened to drain the blood, and the fluid being allowed to run till clear, after which the body was injected with Formula 1, the vein being ligatured.

It occasionally happens that no fluid will pass into one or both legs. They can then be perfectly preserved by suspending the subject and introducing the fluid into the cellular tissue by an aspirator needle thrust deeply into the limb, first in the buttocks, then in the thigh, calf and front of the leg, filling each fascial compartment. Such a body cannot be used for dissection, as the arteries cannot be injected with the colored mass; but it is good for operative surgery.

When the subjects are placed on the dissecting table, the limbs separately and then the whole trunk are wrapped in unbleached domestic dipped in Formula 2, outside of which is wrapped waterproof sheeting made of oiled domestic for the limbs, and oiled duck for the whole subject. A little attention on the part of the student will keep the parts indefinitely. The appearance of any mold calls for temporary immersion in a tank containing Formula 2.

Waterproof sheeting is easily prepared by saturating

domestic or duck with boiled linseed oil and drying, the least possible quantity of oil being used. Such oiled sheets must not be folded up or they will heat and become charred; they must be hung loosely on lines. Lastly, each body has attached to the lobule of the ear a brass tag with a number, the number referring to a record of the name, diagnosis, etc., sent from the hospital, and the record is completed by noting pathological findings in the course of dissection. At the end of a couple of months or more the organs are found in good condition for microscopic examination.

SOME ANOMALOUS CASES OF TYPHOID FEVER.*

By AUGUSTUS A. ESHNER, M.D.,

Professor of Clinical Medicine in the Philadelphia Polyclinic; Physician to the Philadelphia Hospital; Assistant Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases.

In any community provided with a water-supply constantly exposed to the danger of contamination, cases of typhoid fever will always occur, and while, perhaps, no other disease is as common or as well known, the clinician must ever be on the alert lest he overlook mild or anomalous cases or mistake for typhoid other diseases that simulate it. The possibility of confusion is not diminished by the fact that typhoid fever is exceptionally unattended with elevation of temperature, nor that the disease is at times unassociated with intestinal lesions. The liability to error has, however, been much reduced in recent years through the employment of the Gruber-Widal serum-test, which, although it may be considered the most trustworthy among the diagnostic phenomena of typhoid fever, on the one hand, cannot be relied upon at an early stage of the disease, and occasionally fails to yield a positive reaction in genuine cases, while on the other hand a positive reaction may be due to an earlier attack of typhoid unnoticed or forgotten. Even in the absence of the blood-serum reaction it seems yet permissible, though obviously not entirely safe, in temperate climates, to consider as typhoid any continued fever not explicable upon other grounds. The symptoms of the disease will necessarily vary with the degree of virulence of the typhoid-bacilli on the one hand and the degree of susceptibility or immunity of the infected individual on the other hand.

The following cases are briefly reported for the purpose of evoking discussion and a recital of personal experience. The first two are noteworthy for the striking contrast with each other they exhibit, the one being extremely severe and the other unusually mild.

CASE 1.—An unmarried woman, 38 years old, was admitted to the Philadelphia Polyclinic August 22, 1899, after a week's illness, attended with fever, diarrhea, and delirium. She had just come from Atlantic City, where she had been but a short time, and was on her way home to Long Island, whither she had been sent on account of her illness. She had previously been in Washington. Her temperature was 104.8°, the pulse 104, the respirations 28. Her face was flushed and presented a dull, heavy expression. Sordes were present on the teeth, and the tongue was covered with a brownish crust. The abdomen was soft; the spleen enlarged. Heart and liver exhibited no abnormality. No rose spots could be discovered at the time, although they appeared a little later. The patient was in a state of profound depression, with muttering delirium. The urine, examined in the course of a day or two, was found free from albumin and sugar, containing a small amount of indican and yielding the diazo-reaction; and the blood responded positively

to the Gruber-Widal test. Tub-bathing was at once begun in water at a temperature of 68° F. for 10 minutes whenever the temperature in the rectum reached 102.2°, and half an ounce of whisky was given before and after each bath. An ice-bag was applied to the head and one to the abdomen, and $\frac{1}{16}$ grain of strychnin was administered every 3 hours, together with peptonized milk every 2 hours. The temperature persisted at its high level. The bowels moved involuntarily, and the bladder was catheterized on account of failure to void urine normally. On the twenty-third day after admission blood was observed in the stools, and the baths were suspended temporarily, being replaced by sponging with dilute alcohol. Later in the day a hemorrhage of 6 ounces, and subsequently a second of 16 ounces took place from the bowel. Morphine, $\frac{1}{4}$ grain, and ergotin, $\frac{1}{4}$ grain, were given hypodermically. On August 25, sponging for 20 minutes was begun when the temperature was above 102°. Tub-bathing was, however, resumed on the 29th, and was continued as required until September 13. Sixty tubs and 44 sponges in all were given.

The temperature did not begin to waver until August 30. On September 1, it fell below 99°, and thereafter it continued irregular until September 4, when again it reached the 103° level, continuing somewhat irregularly thereafter until October 2, when it once more began to decline; but it did not reach the normal, to remain there, until November 13. Cough was a troublesome symptom from the beginning, but only signs of bronchitis could be discovered until about September 11, when signs of pneumonia at the base of the left lung appeared, with rusty sputum containing diplococci, but no tubercle-bacilli, and after a few days also signs of pleurisy. This condition yielded with extreme reluctance. It was thought the period between September 2 and 15 was occupied by a relapse. On October 10, the urine contained albumin and hyaline and granular tube casts; and on the 24th a slight trace of albumin, without casts, and it yielded the diazo-reaction. On the 12th, the blood responded positively to the Gruber-Widal test. The patient was discharged November 26, completely recovered.

The intoxication in this case evidently was profound, delirium, restlessness, tremulousness, sleeplessness, and nausea being marked features. For a time perforation of the bowel was feared, and the services of a surgeon were held in readiness for needed intervention at a moment's notice. Oxygen-inhalations were employed for a part of the night of August 26, and the morning of August 27.

CASE 2.—A driver, 30 years old, was admitted to the Polyclinic Hospital September 5, 1899, on account of a fracture of the fibula, which received appropriate treatment and pursued an uncomplicated course. The temperature was 100.6° on admission, and continued at this level for a week, when it rose to a slightly higher plane, running between 101° and 103°, in the neighborhood of which it continued for 10 days, when it began gradually to decline, reaching the normal on the twenty-fifth day, and so remaining. Throughout all of this period the patient was perfectly comfortable and made no complaint whatever. The urine was found free from albumin and sugar, and on September 18 it failed to yield the diazo-reaction, although this was found present subsequently, on September 19, and October 6, 12, and 17. No malarial plasmodia were found in the blood, but a positive reaction to the Gruber-Widal test was obtained on September 16 and 18, and again on the 22d. On September 18, there had been nosebleed, the spleen was found enlarged, and rose spots were detected upon the abdomen. The patient was dismissed, perfectly well, on October 24.

The original rise of temperature in this case was attributed to the traumatism inflicted, together with the consequent disturbances attendant upon the fracture, particularly as the general condition was so slightly affected as not to attract the attention of the patient, whose diet had thus far not been specially restricted. The persistence of the pyrexia, however, together with the development of the remaining symptoms, left no doubt as to the diagnosis, although it cannot be asserted

* Read before the Philadelphia County Medical Society, October 21, 1900.

with certainty whether or not the patient was suffering from typhoid fever on admission. The case is noteworthy only for the extreme mildness of the constitutional manifestations throughout.

The next two cases are interesting by reason of their hemorrhagic character. They are to be reported in detail at a later date.

CASE 3.—A heavy drinker, 39 years old, was admitted to the Philadelphia Hospital July 13, 1900, in a delirious state, after an illness of 3 weeks' duration, which the symptoms indicated to be typhoid fever. In the course of a few days a hemorrhagic eruption appeared all over the body; the urine became bloody, and hemorrhage from the bowel took place. Death resulted and blood was found in the peritoneal, pleural and pericardial cavities; in the stomach and intestines; in the bladder, the lungs, the kidneys and their pelves, the adrenal bodies and the pancreas. The ileum, besides, was the seat of typhoid ulceration.

CASE 4.—A laborer, 28 years old, was admitted to the Philadelphia Hospital on July 14, 1900, with symptoms of typhoid fever. Five days later a petechial eruption appeared on the chest and the abdomen and persisted for several days. Death took place on the eighth day of observation, and postmortem examination disclosed the existence of typhoid ulceration of the intestines.

The next case that I shall report I believe to have been one of typhoid fever without intestinal lesions. I was, unfortunately, unable to secure permission for an autopsy, and cannot, therefore, verify the correctness of the diagnosis, which was based upon the presence of the Gruber-Widal reaction and the total absence of intestinal symptoms.

CASE 5.—I was called on August 18, 1900, to see a young man, 19 years old, who had been employed as a waiter and had complained of headache and weakness for a few days. Other than elevation of temperature and slight roughness of breathing, no objective abnormality could be detected, and, apart from a few rosespot and slight enlargement of the spleen, nothing special developed in the further course of the case. On August 20, 24, and 27 the blood failed to yield the Widal reaction; on September 6, clumping was present and an incomplete reaction was obtained; finally, on September 9, the reaction was complete and immediate. Death took place on September 12, from progressive asthenia.

A considerable number of cases of typhoid fever without intestinal lesions have now been reported, and such a diagnosis seems entirely legitimate. Of course, the recognition, as well after death as during life, is possible only by bacteriologic methods, and is to be based upon the presence of typhoid-bacilli in the intestinal discharges or contents or in blood from the spleen, or upon a positive response of the blood to the Gruber-Widal test. When it is reflected that infection with other microorganisms is not confined to a single viscus, it should not occasion surprise that infection with typhoid-bacilli should not be confined to the intestine, and it may safely be concluded, I think, that no organ or tissue exhibits a specific predisposition to infection with any one microorganism. There is, thus, justification for the view that typhoid fever is not inherently an intestinal disorder. That it is so in the vast majority of cases may be due to the mode of infection.

The difficulty in the differentiation between typhoid fever and acute miliary tuberculosis is perfectly well known, the latter disease being the more often mistaken for the former. I have elsewhere dwelt upon the differential diagnosis in connection with the report of a probable case of miliary tuberculosis simulating typhoid fever.¹ I recall, distinctly, however, the case of a boy

at the Philadelphia Hospital during the past summer, who presented symptoms that led me at first to make a diagnosis of miliary tuberculosis as against typhoid fever, but in which, as the disease developed, it became perfectly clear that the latter was the condition really present.

I have within a few days seen a woman in whom premature delivery resulted partly in consequence of an attack of malarial intermittent fever, and partly in consequence of the large doses of quinin administered, and who, after an uncomplicated labor without puerperal infection, developed symptoms of typhoid fever, at the conclusion of which those of intermittent fever reappeared, and these in turn yielded to the administration of quinin.

I wish, finally, to make brief reference to 2 cases previously reported, in which typhoid fever coexisted with two other infections. In one of these typhoid fever developed in a syphilitic subject presenting also symptoms of pulmonary tuberculosis;² in the other typhoid fever developed in the course of pulmonary tuberculosis and was complicated by pneumonia.³

AN UNUSUAL CASE OF ACHYLIA GASTRICA.

By FRANK H. MURDOCH, M.D.,

of Pittsburgh, Pa.

On April 1, 1897, a patient 54 years of age, came to me complaining of loss of appetite, constipation, lassitude and almost constant dull pain in the frontal region. Physical examination revealed nothing wrong excepting gastroptosis, the lower border of the stomach reaching the navel. Examination of the stomach contents showed that the patient was suffering from achylia gastrica, the rennet zymogen even being absent, and subsequent examinations, made at intervals during the year, gave a similar result. Two examinations made in January, 1898, proved that achylia still existed, but now rennet zymogen was present though tardy, curdling not taking place for 3 hours after the addition of the calcium solution. During these 10 months lavage had been used for some time, and afterwards intragastric faradization, which benefited the patient, but had no appreciable effect towards restoring the gastric secretions. At the end of this time all treatment was abandoned as useless, and no examination was made until May 30, 1900, when he came to me complaining that 3 days before, one evening, after supper, he became suddenly dizzy, and had to lie down, and soon afterwards was nauseated and tried to vomit, but did not. For the next three days he continued to feel dizzy, so that he staggered when walking and was unable to work. Examination of the stomach contents showed that free HCl was now present in about normal amount, and has continued so up to the present time.

In this case I am chemically certain that achylia existed for 10 months, and morally certain that there was no gastric juice in this man's stomach for three years, and I believe its unexpected return was responsible for the sudden attack of nausea and vertigo experienced by the patient. Achylia gastrica is a common enough disease, but it is quite unusual for the gastric secretions to be restored after having been absent for so long a time. Hemmeter says: "To our knowledge there is no case of well-authenticated achylia on record in which a cure or an improvement in the neurasthenia was reported to have cured or improved the secretory defect." This case, however, proves that when achylia is due to nervous disturbances, and not to any anatomic change in the gastric mucous membrane, the secretion

¹ *International Medical Magazine*, February 15, 1898.

² *PHILADELPHIA MEDICAL JOURNAL*, March 25, 1899.

³ *American Journal of the Medical Sciences*, July, 1899.

of the gastric juice may be restored after long absence. Einhorn also has reported one case in which the gastric secretions were reestablished after an absence of 5 years.

NEW SLIDE LIFTER AND HOLDER.

By A. H. STEWART, M.D.

Laboratory of Bureau of Health, Philadelphia.

As there is, at the present time, no instrument of this character on the market of any practical value, this instrument, I believe, will prove entirely satisfactory.

The demand for a slide forceps has been brought about by the rapid diagnostic bacteriological work of the clinical and bacteriological laboratories.

Staining on coverslips, although much more cleanly and less dangerous for pathogenic organisms, and, in fact, the only method of making good, permanent mounts, yet it is not absolutely necessary when the consideration of accuracy and time are taken into account.

The general design of this instrument is somewhat similar to the coverslip forceps made for me five years ago, which has become so generally used, and of which several inferior and cheaper modifications have been made to sell to students.

This slide lifter and holder lifts the slide from a glass or wood surface by a sharpened blade and holds it firmly. The slide is prevented from slipping backward upon the body of the forceps by an upward curve of the second blade.

Only about one-half inch of the slide is grasped by the blades of the forceps, which is quite sufficient to hold the slide firmly, and when the slide is heated there is no danger of breakage.

The microscopic slides of the present day are only about one-half as thick as those made only five years ago, and are consequently more difficult to handle.

When a slide is partly covered with stain, in order to lift it with the fingers, the slide must be drawn to the edge of the table.

With these forceps, any thickness of slide, covered with stain, can be lifted without soiling the hands or spilling any stain whatever upon the table or one's clothes.

To use the forceps properly, prevent the slide from moving with the index finger of left hand, and press upon the sides of the forceps, and when the slide is lifted the blades will grasp and hold it firmly.

AMPUTATION OF BOTH FEET. THE LEFT HAND AND THE RIGHT HAND, SAVING THE LITTLE FINGER AND PART OF THE THUMB.

By J. S. WIGHT, M.D., LL.D.,
of Brooklyn, N. Y.

Professor of Operative and Clinical Surgery at the Long Island College Hospital.

JOSEPH GILLIGAN, 6 years of age, having both hands and both feet crushed by a trolley-car, was admitted to the Long Island College Hospital on the afternoon of October 30, 1899.

The shock was very severe. Under treatment he reacted somewhat. On the next day, October 31, I operated, amputating both feet and the left hand, saving the little finger and part of the thumb of the right hand. These amputations were performed in 12 minutes. I was assisted by Drs.

Cochran, Rogers and Rae. On the third day mortification began in the left leg stump. On November 8, I operated on the left lower limb, first disarticulating at the knee-joint, and then, finding the blood-supply imperfect, I amputated at the middle of the thigh. Subsequently the thigh-stump was trimmed and put in better shape. On January 10, 1900, I reoperated on the right leg-stump. On January 31, 1900, I operated again on the left forearm; these reamputations were necessary on account of necrosis of parts of the flaps and the portions of the ends of the bones. No further operation was required on what was left of the right hand. The patient was discharged from the Hospital on April 19, 1900.

It may be noted that a rapid operation may save life by diminishing shock and shortening the time of anesthesia. The primary amputations were performed as rapidly as possible, as well as the amputations for mortification of the left leg. The patient can feed himself with his abbreviated hand. He can also render much aid in putting on and taking off his clothes.

Epigaea for Eructation.—Aaron (*The American Therapist*, September, 1900) recommends epigaea for belching up of tasteless or offensive gases. Epigaea is commonly known as trailing arbutus. The author does not know how the drug acts, but states that he has had many prompt and happy results with it in some very obstinate cases of eructation of gas. He usually prescribes 1 dram of the fluid extract, three or more times a day, after meals. If the eructations be due to fermentation it may be that the aromatic oil acts as anti-ferment, yet results are equally seen in nervous eructation or in cases in which the patient belches up air that has been swallowed.
